Abstract: Nutrient cycling and energy flow in ecosystems are tightly linked through the metabolic processes of organisms. Greater uptake of inorganic nutrients is expected to be associated with higher rates of metabolism (gross primary production (GPP) and respiration (R)), due to assimilatory demand of both autotrophs and heterotrophs. However, relationships between uptake and metabolism should vary with the relative contribution of autochthonous and allochthonous sources of organic matter. To investigate the relationship between metabolism and nutrient uptake, we used whole-stream and benthic chamber methods to measure rates of nitrate-nitrogen ($\text{NO}_3\text{-N}$) uptake and metabolism in four headwater streams chosen to span a range of light availability and therefore differing rates of GPP and contributions of autochthonous carbon. We coupled whole-stream metabolism with measures of $\text{NO}_3\text{-N}$ uptake conducted repeatedly over the same stream reach during both day and night, as well as incubating benthic sediments under both light and dark conditions. $\text{NO}_3\text{-N}$ uptake was generally greater in daylight compared to dark conditions, and while day-night differences in whole-stream uptake were not significant, light-dark differences in benthic chambers were significant at three of the four sites. Estimates of N demand indicated that assimilation by photoautotrophs could account for the majority of $\text{NO}_3\text{-N}$ uptake at the two sites with relatively open canopies. Contrary to expectations, photoautotrophs contributed substantially to $\text{NO}_3\text{-N}$ uptake even at the two closed-canopy sites, which had low values of GPP/R and relied heavily on allochthonous carbon to fuel R.

1 **Introduction**

2 Elemental cycling and energy flow are fundamental ecosystem processes that are tightly
3 linked from the level of the stoichiometry of individual metabolic reactions (Nealson and Stahl
4 1997, Hedin and others 1998) to broad linkages at the level of the whole ecosystem (Redfield
5 1958, Reiners 1986, Elser and others 1996). These links exist because all organisms need both
6 energy and elements for maintenance and growth. Autotrophs generally obtain nutrients from
7 inorganic sources, whereas heterotrophs may obtain nutrients from inorganic forms as well as the
8 organic carbon compounds sequestered as an energy source (Beck and others 1991). For both
9 autotrophs and heterotrophs, low nutrient availability can limit rates of metabolism and,
10 conversely, rates of metabolism ultimately determine rates of nutrient uptake, transformation,
11 and release (Grimm 1987, Vitousek and Howarth 1991, Mulholland and others 1997, Schlesinger
12 1997).

13 Ecosystem studies of streams historically have capitalized on the downstream flow of water
14 to assess either energy flow (Odum 1956, Fisher and Likens 1973, Minshall and others 1983,
15 Meyer and Edwards 1990) or nutrient retention (Webster and Patten 1979, Newbold and others
16 1981, Triska and others 1989, Webster and Meyer 1997) and more recently, both concurrently
17 (Mulholland and others 1997, Hall and Tank 2003, Webster and others 2003). Longitudinal
18 resolution of dissolved oxygen (DO) concentrations over diel temporal scales have been coupled
19 with measures of atmospheric exchange to provide insightful measures of whole-system
20 metabolism (Odum 1956, Grimm and Fisher 1984, Marzolf and others 1994, Young and Huryn
21 1999, Mulholland and others 2001). Similarly, a set of techniques to quantify nutrient cycling in
22 streams has been developed based on the longitudinal transport of materials participating in
23 elemental cycling (Newbold and others 1981, Stream Solute Workshop 1990). The conceptual

basis for these techniques was the recognition that advective flow results in downstream displacement of cycling activities (Webster and Patten 1979), stretching nutrient cycles into spirals oriented parallel to the direction of flow (sensu Elwood and others 1983).

Uptake of inorganic nutrients from the water column is a central component of nutrient retention in streams, and is the aspect of nutrient spiraling most often quantified. Common metrics used to describe uptake include: (a) uptake length (S_w), the average distance traveled by an element in dissolved form, (b) uptake rate (U), the area specific uptake of an element, and (c) uptake velocity (v_f) (Stream Solute Workshop 1990). Uptake velocity has increasingly been used for inter-site comparisons because it accounts for differences in water depth and velocity and, thus, emphasizes biological influence on solute transport and uptake relative to nutrient concentration (Davis and Minshall 1999, Bernhardt and others 2002, Hall and others 2002, Valett and others 2002, Hall and Tank 2003). For linking stream ecosystem metabolism and nutrient uptake, area specific uptake rate is an appropriate measure because both U and metabolism are typically expressed in units of mass of the element of interest per area per time, enabling the stoichiometric link between these processes to be emphasized.

Beyond theoretical interests in nutrient cycling, there is a growing concern about how ecosystems may respond to increased anthropogenic inputs of nutrients, particularly nitrogen (Aber and others 1989, Vitousek and others 1997). Understanding mechanisms and controls of nitrate-nitrogen ($\text{NO}_3\text{-N}$) uptake and retention in aquatic ecosystems is central to this concern. More than 15 years ago, Smith et al. (1987) reported increased $\text{NO}_3\text{-N}$ concentrations as the most evident change in stream and river quality in the U.S.. Vitousek et al. (1997) pointed out that the mechanisms and rates at which ecosystems retain nitrogen remain an area of significant uncertainty. Recently, several studies have suggested that headwater streams are active sites of

1 nitrogen uptake and transformation and can influence catchment exports (Alexander and others
2 2000, Peterson and others 2001a, Mulholland 2004, Bernhardt and others 2005). At the reach
3 scale, the metabolic activity of stream biota has been shown to be an important control on
4 nitrogen uptake (Hall and Tank 2003, Webster and others 2003).

5 In general, nutrient uptake is expected to increase with increasing rates of metabolism due to
6 assimilatory demand, but this relationship varies with the degree of dominance of autotrophic
7 production and the sources of organic matter fueling heterotrophic production. Streams with
8 open canopies can support substantial benthic algal production (Minshall 1978, Fisher and others
9 1982, Hill and others 2001, Mulholland and others 2001), and under these conditions, dissolved
10 inorganic nutrient uptake is likely to be dominated by photoautotrophs. While high rates of
11 heterotrophic production may be supported by this autochthonous carbon, heterotrophic demand
12 for dissolved inorganic nutrients should be relatively low because of the high quality of this
13 organic matter (e.g., low C:N ratio) (Romani and others 1998). If heterotrophic nutrient demand
14 is met by organic substrates, uptake of inorganic nutrients would not be expected to be tightly
15 linked to rates of heterotrophic respiration. On the other hand, nutrient uptake should relate
16 directly to rates of gross primary production (GPP) based on the stoichiometry of biomass being
17 produced and relate indirectly to autotrophic respiration through its relationship with GPP. A
18 tight coupling between GPP and nitrate uptake is also expected because photoautotrophs
19 typically reduce nitrate using reductant generated through photosynthesis (Huppe and Turpin
20 1994).

21 In well-shaded streams, in-stream photoautotrophic activity and, presumably, autotrophic
22 assimilatory demand, are low at most times of the year. The combined effects of stream channel
23 shading and litter deposition result in the dominance of terrestrial carbon inputs in forest stream

organic matter budgets (Webster and Meyer 1997). Heterotrophic bacteria and fungi utilize these allochthonous inputs, but because terrestrial detritus generally has high carbon to nutrient ratios, heterotrophic production requires inorganic nutrient sources to supplement nutrients obtained from organic substrates (Suberkropp 1998, Gulis and Suberkropp 2003). For a given heterotrophic growth efficiency (del Giorgio and Cole 1998), greater rates of respiration are associated with greater production, and therefore are expected to be associated with higher nutrient demand in allochthonous-based ecosystems.

Across stream ecosystems, linkages between nutrient cycling and metabolism should vary predictably with the relative contributions of allochthonous and autochthonous organic matter supply. Because whole-system respiration (R) includes both autotrophic and heterotrophic activity, nutrient uptake should relate robustly to R despite variation in the sources of organic matter. At the same time, nutrient uptake should relate to GPP, but the influence of GPP may be evident only when autochthonous production is a significant energy flow pathway. To test these hypotheses, we investigated the relationship between metabolism and nutrient uptake in four headwater streams chosen to provide contrasts in canopy cover and related differences in the magnitude of GPP and the balance between allochthonous and autochthonous carbon supply. To assess the relative importance of photoautotrophic and heterotrophic processes, we conducted day and night measurements of metabolism and nutrient uptake. Reach scale $\text{NO}_3\text{-N}$ uptake was quantified using multiple short-term solute additions concurrent with whole-stream metabolism measurements. Benthic chamber measurements of uptake and metabolism allowed for the exclusion of deeper sediments and associated heterotrophs, therefore providing a contrast in the degree of autotrophy compared to whole-system measurements. We predicted that 1) autotrophic N demand would appear as greater $\text{NO}_3\text{-N}$ uptake during day compared to night, 2)

the magnitude of difference between day and night uptake would increase with increasing autochthonous contributions (as measured by GPP/R ratio), 3) GPP and uptake would be closely related in ecosystems with substantial autochthonous production, and 4) ecosystem R would be a good predictor of NO₃-N uptake.

Methods

Study Sites: Four study streams were chosen to have similar discharges, but to vary in light availability and therefore presumably vary in rates of GPP and the relative importance of photoautotrophy. All four streams have been sites of previous research addressing stream metabolism and nutrient spiraling (Valette and others 1996, Mulholland and others 1997, Baker and others 2000, Fellows and others 2001) and site characteristics are summarized in Table 1. The study was conducted in summer to increase the relative importance of autotrophic processes: the period of highest algal production at the open canopy sites and farthest in time from the last autumnal leaf fall. All measurements were conducted during a three week period July-August, 1999.

Two sites with low canopy cover were located in high-elevation montane settings in New Mexico, USA. Rio Calaveras (RC) is a first-order stream that flows through a meadow where a sparse stream-side canopy provides little shading, and therefore the stream supports a substantial periphyton community (Peterson and others 2001b, Peterson and others 2001c). Gallina Creek (GC) is a second-order stream that drains a forested catchment in north central New Mexico dominated by spruce and pine. The riparian canopy is moderately open and benthic periphyton is relatively abundant (Fellows and others 2001).

Two sites with closed canopies were located in southeastern deciduous forests of North Carolina and Tennessee, USA. The East Fork of Walker Branch (EFWB) is a first-order stream on the U.S. Department of Energy's Oak Ridge National Environmental Research Park, Tennessee. EFWB is shaded by a relatively dense canopy of second-growth deciduous forest dominated by oak and hickory (Mulholland 1992). Benthic periphyton is sparse throughout most of the year with a short bloom in early spring before canopy development (P. Mulholland, unpublished data). Hugh White Creek (HWC) is a second-order stream at Coweeta Hydrologic Laboratory, North Carolina that drains a granitic catchment containing a mixture of hardwood species with a dense evergreen understory of rhododendron that reduces light to approximately 1% of incident levels (Webster et al. 1997).

Solute additions: Multiple solute additions were conducted at each site during both day and night to provide replicate measures of $\text{NO}_3\text{-N}$ uptake. The additions were conducted over a relatively short period of time (24 to 36 hrs) to avoid changes such as increased discharge that might result from a summer thunderstorm or other precipitation. Solute additions were used to quantify $\text{NO}_3\text{-N}$ uptake and characterize stream hydrologic conditions following methods described in the Stream Solute Workshop (1990). At each site, 4 to 6 stations were established along the study reach. A fluid metering pump introduced a solution of conservative tracer (Cl^- as NaCl) and $\text{NO}_3\text{-N}$ (as NaNO_3) into surface water at a constant rate. Introduction 10 to 20 m upstream of the study reach ensured complete mixing of solute and stream water. Water samples ($n = 2\text{-}3$) taken at each station characterized background conditions prior to each injection. Samples were filtered using glass fiber filters (Whatman GFF, $0.7\ \mu\text{m}$ pore size) either during

collection or within 12-24 hrs. Samples were frozen until analyzed for Cl^- and $\text{NO}_3\text{-N}$ using ion-chromatography (Dionex DX-100, Sunnyvale, CA).

Conservative tracer concentrations at the downstream station were monitored using specific conductance (YSI 30 meter, YSI Inc., Yellow Springs, OH). Solute was injected for 0.75 to 2.5 hours until approximately constant specific conductance was established at the most downstream sampling station (i.e., plateau conditions, sensu Triska and others 1989). Plateau samples ($n = 2-5$) were taken at each station before turning off the injection pump. Sufficient time (> 2 reach travel times) occurred between injections to clear tracer from the study reach.

Time to plateau at RC and GC was relatively short (less than 1 hr) and a total of 6 injections (3 day and 3 night) were conducted within a period of 24 hrs at each of these sites. Time to plateau at EFWB and HWC was > 2 hours. Four injections over 36 hours (2 day and 2 night) were conducted at each of these sites. $\text{NO}_3\text{-N}$ concentrations during the solute additions were elevated relative to background by a factor of 2 ($300 \mu\text{g L}^{-1}$), 15 ($220 \mu\text{g L}^{-1}$), 9 ($250 \mu\text{g L}^{-1}$), and 5 ($130 \mu\text{g L}^{-1}$) at RC, GC, HWC, and EFWB, respectively.

Conservative tracer concentrations were used to determine discharge (Q , L s^{-1}), water velocity (u , m s^{-1}), and dilution due to groundwater input. Discharge was determined by dilution gauging (Gordon and others 1992) using plateau samples. Water velocity (u) was calculated as reach length divided by nominal travel time (i.e., time required for conservative tracer to reach $\frac{1}{2}$ plateau concentration, sensu Triska and others 1989).

Nutrient Spiraling and $\text{NO}_3\text{-N}$ uptake: Reach-scale $\text{NO}_3\text{-N}$ uptake was characterized by nutrient cycling metrics. Three related measures of $\text{NO}_3\text{-N}$ uptake were calculated for each solute

addition (uptake length, uptake velocity, and areal uptake rate) from the longitudinal decline in non-conservative solute according to equation (1):

$$C_x = C_o e^{-kx} \quad (1)$$

where C_x and C_o are background and dilution corrected concentrations of $\text{NO}_3\text{-N}$ at distance x downstream and at the most upstream station, respectively. The longitudinal uptake coefficient (k , m^{-1}) represents the fraction of added nutrient load removed per meter of downstream travel (Stream Solute Workshop 1990) derived from the linear regression of $\ln [\text{NO}_3\text{-N}]$ and distance downstream. S_w is the negative reciprocal of k , with units of length (m). Uptake velocities (v_f , m s^{-1}) for $\text{NO}_3\text{-N}$ were calculated by (2)

$$v_f = \frac{uz}{S_w} \quad (2)$$

where z is stream depth (m) and was derived from discharge by (3)

$$z = \frac{Q}{wu} \quad (3)$$

where w = stream width (m). At HWC, direct measurements of depth ($n = 100$) over the reach were used to derive v_f . Areal uptake rate (U , $\mu\text{g NO}_3\text{-N m}^{-2} \text{ hr}^{-1}$) per unit area of stream bottom was calculated as (4)

$$U = v_f [\text{NO}_3\text{-N}]_{bkg} \quad (4)$$

where $[\text{NO}_3\text{-N}]_{bkg}$ is the mean background $\text{NO}_3\text{-N}$ concentration.

In the case of one nighttime solute addition at Rio Calaveras, concentrations of nitrate did not decrease downstream after accounting for background concentration and dilution. Uptake rate was assumed to be below detection limit for this one injection, and both U and v_f were assigned a value of zero.

Whole-stream metabolism: Whole-stream metabolism was measured using a modified open channel method (Odum 1956, Marzolf and others 1994). Dissolved oxygen (DO) concentrations were measured at an upstream and downstream station (1-5 min intervals, 36-60 hrs) with YSI 600XLM meters equipped with rapid-pulse oxygen sensors. Barometric pressure was concurrently logged every 5 minutes using a barometer and datalogger (Campbell CR-10, Logan, UT). Photon flux density ($\mu\text{mol m}^{-2} \text{s}^{-1}$) of photosynthetically active radiation (PAR) was measured using a LI-COR quantum sensor (5 min average values, LI-COR Inc., Lincoln, NE) positioned immediately next to the stream channel in the middle of the reach. Daylight hours were identified by $\text{PAR} > 0.3 \mu\text{mol m}^{-2} \text{s}^{-1}$ and were used to determine daily total photon flux.

Oxygen reaeration coefficients were determined using the addition of a dissolved volatile tracer (propane) (Marzolf and others 1994, Young and Huryn 1998) during one of the solute additions at each site. Plateau was judged to be reached using the conservative solute tracer, and samples of stream water then were collected in 60 mL plastic syringes at three or more sampling stations. An equal volume of gas (either air or argon) was added to the syringe, and the syringe shaken to promote headspace equilibration. Headspace propane concentrations were determined in the laboratory using a gas chromatograph equipped with a flame ionization detector (Shimadzu GC-9A, Torrance, CA). Reaeration coefficient ($k_{\text{propane}}, \text{min}^{-1}$) was determined following standard procedures described by Marzolf et al. (1994), converted to k_{oxygen} , and multiplied by the oxygen deficit and reach travel time to calculate oxygen flux due to reaeration.

Effects of groundwater inputs on metabolism measures (McCutchan and others 1998, Mulholland and others 2001, McCutchan and others 2002) were quantified using lateral inflow ($Q_{\text{upstream}} - Q_{\text{downstream}}$, sensu Triska and others 1989, Stream Solute Workshop 1990) and subsurface DO concentrations. Groundwater DO was measured in shallow (< 50 cm depth)

1 near-stream wells. Groundwater DO was determined from a well network in the adjacent
2 catchment of West Fork of Walker Branch at EFWB (P. Mulholland, unpublished data).
3 Accordingly, groundwater DO concentrations were set at 1 ppm for HWC, 2 ppm for GC, 3 ppm
4 for RC, and 7 ppm for EFWB.

5 Once corrected for groundwater inputs and atmospheric exchange, changes in DO during the
6 night represent ecosystem R, while day time changes reflect rates of net ecosystem productivity
7 (Marzolf and others 1994). Measures were scaled to a 24 hr period of time by calculating the
8 sum of all the time intervals for R plus an estimate of daytime R for each interval during the day
9 derived from linear regression of pre-dawn and post-dusk R values (Marzolf and others 1994).
10 GPP was determined as the sum of daytime intervals plus calculated daytime R. Relative
11 magnitude of primary production and respiration was assessed by calculating GPP/R ratios
12 (sensu Odum 1956). Net ecosystem production (NEP) was calculated as the difference between
13 GPP and R over a 24 hr period of time. For EFWB and HWC, metabolic measures were
14 averaged from two consecutive 24 hour periods.

15
16 *Benthic chamber measurements of metabolism and NO₃-N uptake:* Benthic chambers (sensu Bott
17 and others 1978) were used to assess metabolism and NO₃-N uptake at ambient NO₃-N
18 concentrations. Chamber measurements were conducted at each site during the same week that
19 whole-stream measures were made. Plastic trays (85 cm², 2 cm depth) filled with benthic
20 sediment were placed in the stream bed at least 3 weeks prior to use. For each stream, four trays
21 were incubated separately in re-circulating metabolic chambers (Truckee River model, Rapid
22 Creek Research, Inc., Boise, ID) submerged in the stream to moderate temperature fluctuations.
23 Dark and light incubations were run consecutively and dark conditions were achieved by

covering the chambers with opaque material. Chambers were equipped with DO sensors (Orion Model 840, Thermo Electron, Water Analysis/Orion Products, Beverly, MA) and incubations lasted until detectable changes in DO were observed (ca. 2-4 hrs under dark or light conditions). Light incubations were conducted between the hours of 10 am and 2 pm. During light incubations, PAR was recorded every five minutes (LI-COR quantum sensor). DO concentrations and temperature also were measured every five minutes.

Chamber R and NEP were calculated from the slope of the linear regression of DO and time during dark and light incubations, respectively. GPP was calculated as $NEP + R$. Metabolism rates were converted to $g\ O_2\ m^{-2}\ hr^{-1}$ using tray surface area and chamber volume (2 L). A subsample from each sediment tray was analyzed for organic matter (OM) as ash-free dry mass (AFDM, APHA and others 1992). Sediment chlorophyll *a* was determined on a different subsample using extraction with buffered acetone and a standard spectrophotometric (Hewlett-Packard HP8452A, Hewlett-Packard Corporation, Palo Alto, CA) procedure (Wetzel and Likens 1991).

Daily benthic metabolic rates were generated by scaling chamber R to 24 hours and GPP to the total number of daylight hours, while accounting for differences between daily insolation and light levels during chamber incubations. Whole-stream data were used to establish instantaneous GPP versus irradiance curves. Values of maximum photosynthesis and irradiance at the onset of photosaturation were visually estimated from these plots and used to adjust chamber GPP during daylight hours. Daily NEP was calculated by subtracting daily R from daily GPP.

Changes in chamber water NO_3 -N concentrations during benthic sediment incubations were used to quantify NO_3 -N uptake. Water samples were taken 15-30 minutes after initiating recirculation, at the end of the dark incubation, and at the end of the light exposure period.

1 Filtered (Whatman GFF, 0.7 μm pore size) samples were frozen until analyzed using ion-
2 chromatography (Dionex DX-100).

3
4 *Data Analysis:*

5 Nitrate uptake was reported as both v_f and U for whole-stream measures and as areal uptake
6 rate from benthic chamber measurements. Uptake velocity is considered appropriate for
7 comparisons across sites, particularly when water depth and velocity vary. However, v_f is
8 highly dependent on nutrient concentrations, and U may be a more suitable metric for comparing
9 streams with very different nutrient concentrations. Whole-stream areal uptake rates allowed
10 meaningful comparisons to be made with benthic chamber measurements as well as with rates of
11 metabolism. Both U and v_f were expected to increase with increasing metabolism. Biotic
12 demand for N should increase as rates of metabolism increase, which would result in a greater
13 mass of $\text{NO}_3\text{-N}$ being consumed per unit area. If concentrations of $\text{NO}_3\text{-N}$ are relatively
14 constant, then v_f should follow the same pattern as U . Uptake velocity would also be predicted to
15 increase with increasing metabolism, independently of its relationship with U . Because v_f
16 represents the efficiency of $\text{NO}_3\text{-N}$ uptake relative to its concentration in the water column, it
17 should be greater with higher rates of GPP and R because organisms should have more energy
18 available to allocate to the uptake and reduction of $\text{NO}_3\text{-N}$.

19 One-way analyses of variance were used to determine if $\text{NO}_3\text{-N}$ uptake differed among sites.
20 Separate ANOVAs were conducted for each measure of uptake (v_f , U , and benthic uptake) with
21 site as the main factor (4 levels) and either multiple solute additions at each site as replicates ($n =$
22 4-6/site) or chambers as replicates ($n = 3$ or 4/site). ANOVAs were also conducted on chamber
23 measures of metabolism, sediment organic matter (AFDM), and chlorophyll standing crop.

1 Significant ANOVA results were followed by Tukey's multiple comparison test (MCT) to test
2 for differences among sites.

3 Within each site, one-tailed t-tests were performed for each measure of $\text{NO}_3\text{-N}$ uptake to test
4 the prediction that uptake was significantly greater during the day than during night. Benthic
5 chamber values under light and dark conditions were analyzed using one-tailed paired t-tests
6 (paired by chamber, $n = 3$ or 4). Two-tailed t-tests were used to determine if there were day-
7 night differences in physical and chemical aspects of the streams. Linear regression analysis
8 was used to determine if the magnitude of the day-night differences in $\text{NO}_3\text{-N}$ uptake (v_f , U , and
9 benthic uptake; $n = 4$) increased with increasing GPP/R (whole-stream or mean benthic chamber
10 values).

11 Linear regression analysis was also used to assess relationships between $\text{NO}_3\text{-N}$ uptake and
12 metabolism. Measures of $\text{NO}_3\text{-N}$ uptake obtained from a specific solute injection were paired
13 with an associated measure of ecosystem metabolism. Appropriate metabolic measures were
14 obtained by treating each period of solute injection as an experimental unit. Hourly metabolic
15 rates were calculated as the average of all intervals within the designated time. All solute
16 additions ($n = 20$) were used to examine relationship between $\text{NO}_3\text{-N}$ uptake and R and only
17 daytime additions ($n = 10$) were used for GPP. For benthic chamber measurements, regression
18 analyses were performed between dark and light $\text{NO}_3\text{-N}$ uptake and R ($n = 25$) and light $\text{NO}_3\text{-N}$
19 uptake and GPP ($n = 13$). For whole-stream and benthic chamber uptake and GPP, regression
20 analyses were repeated using only the two sites with open canopies/high autochthonous
21 contributions to compare these relationships with those including all sites. All statistical
22 analyses were carried out with $\alpha = 0.05$ using SAS, Version 8 (1999).

Results

Hydrologic and other physical conditions: Three of the sites had very similar values for discharge, each averaging approximately 1 L s^{-1} , while HWC had a greater value at 3.4 L s^{-1} (Table 2). All streams were shallow (mean depth $1.8 - 7 \text{ cm}$) and velocity varied four fold from 0.013 m s^{-1} for EFWB to 0.053 m s^{-1} for RC. Wetted channels were generally 1 m wide, except at HWC where the much wider stream channel ($> 5 \text{ m}$) corresponded to an average depth of less than 2 cm .

Mean temperature and background $\text{NO}_3\text{-N}$ concentration varied across sites, but day-night differences within sites were not significant in all cases (t-test, $p > 0.05$; Table 2). Mean temperatures were approximately $5\text{-}6^\circ\text{C}$ greater in the closed canopy streams (17 and 18°C) compared to the high elevation streams in New Mexico (11.7 and 12.5°C). Background $\text{NO}_3\text{-N}$ concentrations varied an order of magnitude from highest to lowest, with values of $168 \mu\text{g l}^{-1}$ at RC to $14 \mu\text{g l}^{-1}$ at GC. Background concentrations were intermediate in magnitude at the two other streams (both $28 \mu\text{g l}^{-1}$).

Daily PAR values reflected the degree of canopy cover with the highest value of $20.0 \text{ mol m}^{-2} \text{ d}^{-1}$ at RC to 0.1 at HWC (Table 3). The number of daylight hours at each site varied from 11.2 at HWC to 14.7 at RC.

Metabolism: Whole-stream and benthic chamber values of GPP and GPP/R were much greater at the two open-canopied sites (RC and GC) than at the two closed-canopied sites (EFWB and HWC)(Tables 3 and 4). All 4 study streams were heterotrophic systems, but the extent to which R exceeded GPP varied. RC and GC had GPP/R ratios that were an order of magnitude greater than EFWB and HWC. The magnitude of the inter-site differences for benthic chamber GPP/R

was smaller, but values at RC and GC were significantly greater than those at EFWB and HWC (ANOVA, $p = 0.001$). Benthic chamber values of GPP/R exceeded 1 at RC and GC and were substantially greater than whole-stream values for each site except HWC.

Light versus dark $\text{NO}_3\text{-N}$ uptake: Whole-stream $\text{NO}_3\text{-N}$ uptake was greater during the day than at night at all four sites for v_f and U (Figure 1), but none of the differences was statistically significant. The magnitude of the difference between day and night, relative to the mean value for the site, was relatively small for GC and HWC, ranging from 14 to 24% (Table 5). Day-night differences for both metrics were substantially greater at EFWB and RC, with values of over 60% of the mean for EFWB and over 90% for RC.

Within each site, benthic chamber $\text{NO}_3\text{-N}$ uptake rates were significantly greater in light conditions than in dark conditions (Figure 1; one-sided paired t-test, p values RC = 0.050, EFWB = 0.013, HWC = 0.033), with the exception of GC where there was only one chamber from which both light and dark rates had been obtained (chamber $\text{NO}_3\text{-N}$ concentrations dropped below detection limit during some of the incubations). Benthic chamber uptake rates were consistently negative (increase in $\text{NO}_3\text{-N}$ concentration) at HWC and EFWB, but $\text{NO}_3\text{-N}$ production was greater during the night, resulting in higher values of uptake (less negative) during the day.

There were no discernable trends between the magnitude of day-night differences in uptake and the importance of autochthonous production. None of the relationships between day-night differences in uptake (whole-stream v_f and U , and benthic uptake) and GPP/R were significant. However, the magnitude of the day-night differences in uptake was generally greater

for chamber measurements compared to whole-stream measurements, with the exception of GC (Table 5).

Relationships between metabolism and NO₃-N uptake: Nitrate uptake generally increased with increasing metabolism, for both whole-stream and benthic chamber measures, but the relationships between uptake metrics and measures of metabolism varied greatly. Contrary to expectations, R was not a particularly good predictor of NO₃-N uptake. Additionally, GPP and uptake appeared to be closely related when all sites were considered, and the relationships were not stronger when the sites with low autochthonous contributions were excluded.

Whole-stream NO₃-N uptake as measured by v_f generally increased with increasing metabolism, but there were no discernable relationships between U and metabolism (Figure 2).

Whole-stream v_f increased with increasing GPP, and the strength of the relationship was similar when all sites were considered ($p = 0.002$, $r^2 = 0.72$, $n = 10$) or when only the two sites with substantial autochthonous production were considered ($p = 0.021$, $r^2 = 0.78$, $n = 6$). When a potentially influential point was removed (highest GPP) the relationships were still significant ($p = 0.018$, $r^2 = 0.57$, $n = 9$; $p = 0.050$, $r^2 = 0.77$, $n = 5$). Whole-stream U did not exhibit a significant relationship with GPP for all sites or just RC and GC. Whole-stream v_f showed a significant positive relationship with R when all sites were considered ($p = 0.006$, $r^2 = 0.36$, $n = 20$). However, the regression was influenced by a clustering of points with low v_f and low R, and at higher values of R, the spread of GC points is suggestive of a negative slope. Similar to the findings for GPP, whole-stream U did not exhibit a significant relationship with R. Within the pair of sites with higher GPP/R values, GC, the site with the higher GPP/R and GPP values of the pair, had higher mean values of v_f and U , and the difference was significant for v_f (ANOVA,

p<0.0001; Table 3). Within the pair of sites with lower GPP/R values, EFWB, the site with higher rates of GPP and R, had higher mean values of v_f and U than HWC, but the differences were not significant.

Nitrate uptake in benthic chambers increased with increasing rates of metabolism, and the strongest relationship was between uptake and GPP across all sites (Figure 2; $p = 0.0001$, $r^2 = 0.84$, $n = 13$). When only values from RC and GC chambers were considered, the relationship was weaker but still significant ($p = 0.050$, $r^2 = 0.65$, $n = 6$). The relationship between uptake and R across all sites was significant but relatively weak ($p = 0.0008$, $r^2 = 0.39$, $n = 25$). With the removal of two influential points with the highest R values, the relationship was somewhat steeper (slope of 22.7 compared to 13.0) but still significant ($p = 0.004$, $r^2 = 0.33$, $n = 23$).

Discussion

Importance of autochthonous versus allochthonous contributions: Different rates of GPP generated a range in the quantity of autochthonous carbon available across the four study streams, and values of GPP/R suggested that the balance between autochthonous and allochthonous carbon sources also varied. To assess the relative importance of autochthonous carbon at the sites, values of GPP/R were compared to the transitional P/R (Rosenfeld and Mackay 1987, Meyer 1989). The transitional P/R has been suggested as a way of characterizing the dependence of the heterotrophic community in a stream on autochthonous versus allochthonous sources of carbon. At $GPP/R < 0.5$, R must be supported more by allochthonous than autochthonous sources of carbon, whereas at $GPP/R > 1$, R must be supported more by autochthonous than allochthonous sources. Using these guidelines, the relative importance of autochthonous carbon at the sites matched expectations based on canopy cover/light availability.

Both whole-stream and benthic chamber measurements for the closed-canopy sites (HWC and EFWB) indicated that these streams are primarily reliant on allochthonous sources of carbon (GPP/R from 0.03 to 0.17). Whole-stream GPP/R values for the open-canopied sites (RC and GC) were both close to the transitional value of 0.5, indicating an important role for both sources of organic matter. Benthic chamber values of GPP/R for RC and GC were greater than one, and were the only circumstances under which the systems were primarily dependent on autochthonous carbon. Except for HWC, benthic chamber measurements at each site showed greater reliance on autochthonous carbon than whole-stream measurements.

The range in relative importance of autochthonous and allochthonous carbon observed across the sites provided the opportunity to test predictions on how this balance should influence relationships between $\text{NO}_3\text{-N}$ uptake and metabolism, including day-night differences. Based on values of GPP/R, a strong photoautotrophic contribution to uptake would not be expected in EFWB and HWC, but would be likely in RC and GC, especially for the benthic chambers. Large light-dark differences in uptake would be expected for RC and GC, as well as a tighter relationship between uptake and GPP for these two sites compared to all sites. Some, but not all of these predictions were met. Photoautotrophs played a greater role than was expected at the two closed-canopy sites, while their influence was not as great as expected at the two open canopy sites.

Contribution of photoautotrophs to $\text{NO}_3\text{-N}$ uptake: Photoautotrophs appeared to influence uptake at all four sites, despite low values of GPP/R at two sites. Uptake was greater in daylight than in the dark for both whole-stream and benthic chamber measurements in most cases. While there were no significant differences between daytime and nighttime whole-stream uptake,

1 daytime means were greater in magnitude at all sites for both uptake metrics. The observed day-
2 night differences in uptake were likely due to photoautotrophic activity and not differences in
3 temperature, $\text{NO}_3\text{-N}$ concentration, or discharge, because day-night differences in these
4 physical/chemical variables were small and not statistically significant. The lack of significant
5 day-night differences, despite the importance of autochthonous production at RC and GC, may
6 be due to photoautotrophic uptake occurring during both day and night. Light enhances uptake
7 of $\text{NO}_3\text{-N}$ by algae that use reductant generated during photosynthesis, but uptake can also occur
8 in the dark when algae use stored carbon compounds (Abrol and others 1983, Huppe and Turpin
9 1994). A lack of diel variation in $\text{NO}_3\text{-N}$ uptake might also be seen if the magnitude of
10 assimilation by photoautotrophs was small relative to other processes (e.g., heterotrophic
11 assimilation), or rates were changing within day and night periods.

12 Benthic $\text{NO}_3\text{-N}$ uptake rates were significantly greater in incubations conducted under
13 light conditions compared to dark conditions for three of the four sites, reinforcing the trend
14 observed for the whole-stream rates. Photoautotrophic influences should be more dominant in
15 benthic sediment chambers compared to whole stream reaches due to the exclusion of
16 heterotrophs associated with deep sediments (Grimm and Fisher 1984, Naegeli and Uehlinger
17 1997, Fellows and others 2001). Furthermore, differences in benthic rates may have been easier
18 to detect because replicate chambers were run at the same time of day, in contrast to whole-
19 stream measures that were made at different times of day. Gallina Creek was the only site at
20 which the light-dark difference in rates was not significant, but it is likely that the incubations at
21 this site did not represent an accurate assessment of benthic community uptake. Chamber $\text{NO}_3\text{-}$
22 N concentrations were already below ambient concentrations by the time the first water samples
23 were collected, and final samples were below detection limit in several cases. As a result,

1 measured rates are probably underestimates, and it is possible that benthic sediments at GC
2 would have shown light-dark differences if uptake rates had been consistently detectable. In
3 $\text{NO}_3\text{-N}$ -amended chamber incubations conducted at this site for a different purpose, light
4 incubations had higher uptake rates than dark incubations ($8,250 \pm 1430 \mu\text{g NO}_3\text{-N m}^{-2}\text{hr}^{-1}$
5 compared to $5,005 \pm 739 \mu\text{g NO}_3\text{-N m}^{-2}\text{hr}^{-1}$, Fellows 2000). In EFWB and HWC, $\text{NO}_3\text{-N}$
6 release occurred during light and dark conditions, but rates were lower (i.e., uptake less negative)
7 during light conditions. Although light-dark differences in nitrification rates could result in this
8 difference, it is likely that lower rates of $\text{NO}_3\text{-N}$ release under light conditions was due to
9 photoautotrophic uptake, because no day-night differences in stream water $\text{NO}_3\text{-N}$
10 concentrations were observed.

11 Benthic chamber light-dark differences in uptake were generally greater than those for
12 whole-stream measures, supporting the prediction that the magnitude of day-night differences
13 would increase with increasing autochthonous contributions. However, across sites, variation in
14 the magnitude of day-night differences was not explained by GPP/R ratios. Light-dark
15 differences in uptake for GC and EFWB did not follow the expected ranking based on increasing
16 autochthonous contributions: greater day-night differences were expected for GC and smaller
17 differences for EFWB. Low stream water $\text{NO}_3\text{-N}$ concentrations at GC precluded detection of
18 light-dark differences in chamber incubations, and also may explain why the relative magnitude
19 of whole-stream day-night differences were not greater. With high rates of GPP and R at GC,
20 metabolic demands are likely to be high relative to $\text{NO}_3\text{-N}$ availability, and may lead to
21 consistently high allocation of resources to N uptake by both autotrophs and heterotrophs
22 throughout the day. The idea that $\text{NO}_3\text{-N}$ uptake is very efficient at this site is reinforced by the
23 significantly higher values of v_f at GC compared to the other sites. The pair of closed-canopy

streams had the same $\text{NO}_3\text{-N}$ concentrations as each other and very similar GPP/R ratios, but much larger day-night differences in uptake were observed at EFWB compared to HWC. Rates of GPP were greater in EFWB for both whole-stream and benthic chambers, and even though R was also large, photoautotrophic activity appears to have made a large enough contribution to total uptake to cause day-night differences.

In addition to looking for day-night differences in $\text{NO}_3\text{-N}$ uptake, the role of photoautotrophs can also be assessed by the magnitude of their contribution to total $\text{NO}_3\text{-N}$ uptake. Using published stoichiometry values to link metabolism and nutrient assimilation, photoautotrophic demand for N was estimated and compared with measured $\text{NO}_3\text{-N}$ uptake. We assumed a molar C:N content of algal biomass of 12:1 (Grimm 1985, Dodds and Prisco 1990, Webster and others 2003) to calculate a predicted rate of autotrophic N assimilation for each site from values of whole-stream and chamber net primary production (NPP). NPP was assumed to be 50% of GPP (Odum 1957, Webster and Meyer 1997) and the photosynthetic quotient was set to 1 (i.e., 1 mol O_2 produced : 1 mol CO_2 fixed). Measured $\text{NO}_3\text{-N}$ uptake rates were scaled to 24 hours and then plotted against calculated photoautotrophic demand and compared to a 1:1 line (Figure 3). Values of calculated demand were substantial relative to measured uptake, except for the negative chamber uptake values for EFWB and HWC. Whole-stream uptake was very similar to calculated demand for RC. Measured $\text{NO}_3\text{-N}$ uptake in benthic chambers for GC and RC, as well as whole-stream values for GC, were below the 1:1 line, suggesting that assimilation exceeded measured $\text{NO}_3\text{-N}$ uptake. In contrast, EFWB and HWC whole-stream uptake was greater than estimated autotrophic assimilation. At these two sites, benthic chamber $\text{NO}_3\text{-N}$ release exceeded autotrophic demand.

1 The comparison of estimated rates of photoautotrophic assimilation with measured $\text{NO}_3\text{-N}$
2 N uptake rates enable some broad generalizations to be drawn about the relative importance of
3 this process and other processes affecting $\text{NO}_3\text{-N}$ uptake at the sites. Values of $\text{NO}_3\text{-N}$
4 assimilation by photoautotrophs that equal or exceed 100% of measured values, such as RC and
5 GC whole-stream and chamber rates, suggest that this process may dominate uptake. Failure to
6 detect significant day-night differences at these sites therefore was not likely due to autotrophic
7 uptake being small in magnitude compared to total uptake. When values exceed 100%, another
8 source of N (e.g., $\text{NH}_4\text{-N}$) or production of $\text{NO}_3\text{-N}$ via nitrification may be important to meet
9 assimilatory demand. Estimates of photoautotrophic assimilation that are less than 100% of
10 observed uptake, as was the case for whole-stream uptake at HWC and EFWB, suggest that other
11 processes are involved in $\text{NO}_3\text{-N}$ uptake, such as heterotrophic assimilation and/or
12 denitrification. On the other hand, with values of 50 and 39%, photoautotrophic uptake appears
13 to be a significant process even in these forest streams, at least during summer when the study
14 was conducted. This is consistent with the suggestion by Hall and Tank (2003) that
15 photoautotrophs are likely more important than heterotrophs in $\text{NO}_3\text{-N}$ uptake based on their
16 study of whole-stream $\text{NH}_4\text{-N}$ and $\text{NO}_3\text{-N}$ uptake in 11 Wyoming streams.

17 Nearly all published examples of short-term solute additions have been conducted during
18 the day (but see Martí et al. 1994). Based on the results from this study, measurements of whole-
19 stream $\text{NO}_3\text{-N}$ uptake from daytime additions would slightly overestimate uptake when scaled to
20 24 hrs. For the four sites in this study, multiplying the mean daytime value of U by 24 hours
21 results in values that exceed those calculated using both day and nighttime additions by 6% for
22 GC, 10% for HWC, 25% for EFWB, and 37% for RC. One other study has reported on day-
23 night differences in whole-stream nutrient uptake, and found significant differences in day and

night uptake rates for $\text{NH}_4\text{-N}$ and phosphate in La Solana, a Mediterranean stream in Spain (Martí and others 1994).

Relationships between $\text{NO}_3\text{-N}$ uptake and metabolism: Nutrient uptake should increase with increasing rates of metabolism due to assimilative demands of in-stream biota, but predictions based on this general hypothesis were not consistently met in this study. We predicted increasing uptake with increasing GPP, especially in systems with substantial autochthonous production, and expected R to be a good predictor of uptake across all systems. No relationships between U and metabolism were observed, and relationships between v_f or benthic uptake and R were weak. Relationships between v_f or benthic uptake and GPP were stronger than those with R, but were not improved by excluding sites with low autochthonous production.

The two previous studies that have investigated both whole-stream N uptake and metabolism in multiple streams, Hall and Tank (2003) and Webster et al. (2003), also found variation in the strength of relationships between uptake and metabolism. In a study of $^{15}\text{N-NH}_4$ uptake in 11 streams across multiple biomes, U ranged ca. one order of magnitude among streams but did not show a relationship with metabolism (Webster and others 2003). Furthermore, Webster et al. (2003) found no significant relationships between any measure of uptake (i.e., S_w , v_f , U) and any metabolic parameter. However, N demand calculated from NPP, microbial production, and measured detrital C:N ratios compared reasonably well to measured assimilative N uptake ($\text{NH}_4\text{-N}$ and $\text{NO}_3\text{-N}$). They argued that the multiple mechanisms of nitrogen uptake must be taken into account when seeking a relationship between uptake and metabolism. In contrast, Hall and Tank (2003) found that GPP was related to v_f for $\text{NO}_3\text{-N}$, and that both GPP and R were related to v_f for $\text{NH}_4\text{-N}$ for 11 Wyoming streams. They suggested

1 that these strong relationships stem from the close geographic proximity of their sites and the
2 higher observed variation in v_f compared to Webster et al. (2003). The strongest relationship
3 among whole-stream measures for our four streams was between v_f and GPP, and the
4 relationship with R was weak but significant. Predictions of total assimilative N uptake should
5 approach measured values as calculations become more detailed, including individual uptake
6 processes, and C:N ratios of organisms. However, many of these values, such as heterotrophic
7 growth efficiency and the ratio between NPP and GPP are taken from the literature as opposed to
8 being site-specific, and the detail of study required at each site to some extent precludes the
9 inclusion of a large number of sites. The relationships between uptake and metabolism may be
10 too complex to allow detection of simple linear relationships in some cases, but it is still
11 worthwhile to consider the circumstances under which relationships might emerge.

12 The tightest relationships between $\text{NO}_3\text{-N}$ uptake and a single metric of metabolism
13 would be expected at either end of the spectrum of the importance of autochthonous versus
14 allochthonous carbon sources. In systems dominated by autochthonous carbon contributions,
15 total ecosystem uptake of inorganic N will be dominated by autotrophic uptake. A tight
16 relationship between total uptake and GPP is predicted, through autotrophic assimilation, with
17 the slope of the relationship influenced by the C:N of the autotroph. Because GPP and
18 autotrophic R are related, there will also be a tight relationship between uptake and autotrophic
19 R. With heterotrophic R primarily fueled by autochthonous carbon sources, most heterotrophic
20 N demand should be met from N contained in these low C:N substrates. This results in a weak
21 relationship, if any, between heterotrophic N uptake and heterotrophic R. In contrast, in
22 allochthonous-dominated systems, heterotrophs using these high C:N carbon sources will need to
23 take up inorganic N. A tight relationship between heterotrophic uptake and R therefore is

1 expected, with the slope depending on the C:N of the substrate being degraded. Autotrophic
2 activity will be low, and total ecosystem N uptake will not show a relationship with GPP because
3 heterotrophic uptake dominates. The predicted importance of C:N ratios in influencing the
4 relationship between uptake and metabolism for both autotrophs and heterotrophs is consistent
5 with the findings of Dodds et al. (2004), who reported that C:N ratio explains a substantial part
6 of the variation in N-specific uptake rates of organisms and detritus across a number of terrestrial
7 and aquatic ecosystems. When both autochthonous and allochthonous sources of carbon are
8 important, relationships between ecosystem uptake and metabolism are likely to be blurred
9 because of the lack of dominance of either autotrophic or heterotrophic uptake, and the influence
10 of having a mix of detrital components with different C:N ratios. To test the relationships
11 suggested by this conceptual model, autochthonous or allochthonous-dominated systems could
12 be targeted based on a priori knowledge of GPP/R ratios. One limitation to testing this model is
13 the uncertainty associated with separating ecosystem R into autotrophic and heterotrophic
14 components, which is currently done by assuming that autotrophic R represents a fixed fraction
15 of GPP.

16 Simple linear relationships between uptake and metabolism are predicted based on the
17 assumption of constant C:N ratios, but work in lake ecosystems suggests that systematic changes
18 in stoichiometry might be seen with changes in light and nutrient availability (Sterner and others
19 1997, Sterner and Elser 2002). Sterner et al. (1997) found that as the ratio between light and P
20 availability increased, so did the ratio of C:P in biomass. If the C:N ratio of new autotrophic
21 biomass increases with increasing light/nutrient ratios, a flattening of the relationship between
22 uptake and GPP would be seen, with higher values of GPP having lower than expected uptake.
23 If this were the case for GC which had very low $\text{NO}_3\text{-N}$ concentrations, a higher C:N value

1 would reduce the calculated autotrophic demand, effectively moving the points on Figure 3 to
2 the left, closer to the value of measured uptake. It also might explain the trend of decreasing
3 uptake with increasing R for GC and EFWB in Figure 2. Since the concept of the light/nutrient
4 ratio was developed in lakes, using total phosphorus as a metric of nutrient availability, further
5 work in streams is needed, especially to decide what an appropriate measure of nutrient
6 availability would be.

7 Assimilatory uptake is the focus of this and other studies that have investigated
8 metabolism and N uptake, but dissimilatory processes, such as denitrification and nitrification,
9 may be quantitatively important in some stream ecosystems. Denitrification would show a
10 positive relationship with production of carbon dioxide, but not necessarily any relationship with
11 consumption of oxygen, since it is an anaerobic respiratory process. Denitrification therefore
12 could increase uptake beyond what would be predicted based on rates of metabolism. Most
13 studies assume denitrification is a relatively small component of $\text{NO}_3\text{-N}$ uptake in the oxic
14 environment of streams, especially streams with low $\text{NO}_3\text{-N}$ concentrations (e.g. Hall and Tank
15 2003, Webster and others 2003). A recent study by Mulholland et al. (2004) using an addition of
16 $^{15}\text{N}\text{-NO}_3$ has confirmed that this is the case for EFWB. On the other hand, the importance of
17 nitrification in streams has been shown to vary greatly, from below detection to close to 100% of
18 measured $\text{NH}_4\text{-N}$ uptake (Bernhardt and others 2002, Webster and others 2003). Nitrification
19 consumes oxygen while producing $\text{NO}_3\text{-N}$, increasing the apparent rate of R and possibly
20 causing an underestimation of assimilatory uptake. Neither nitrification nor denitrification can
21 be quantified using solute additions of non-labeled $\text{NO}_3\text{-N}$, in which measured uptake reflects the
22 net demand resulting from the interaction of all organisms present. However, nitrification was
23 observed in this study when benthic sediments were isolated in chambers at the two closed-

1 canopy streams. Recent studies on nitrification in streams have focused on factors that allow
2 nitrifiers to successfully compete with heterotrophs for $\text{NH}_4\text{-N}$, including availability of labile
3 organic carbon (Strauss and Lamberti 2000, Bernhardt and others 2002, Bernhardt and Likens
4 2002, Strauss and Lamberti 2002) and the concentration of $\text{NO}_3\text{-N}$ (Bernhardt and others 2002).
5 Low-availability of labile organic carbon can allow nitrifiers to out-compete heterotrophs
6 (Strauss and Lamberti 2000, 2002). Since rates of GPP are low at EFWB and HWC, and our
7 measurements in August were approximately 10 months since last autumnal leaf fall, labile
8 organic carbon availability was likely to have been low and may be a factor contributing to the
9 observed benthic nitrification.

10 Our results add to the growing number of studies confirming the importance of small
11 streams in reducing loads of dissolved inorganic N being transported downstream (Alexander
12 and others 2000, Peterson and others 2001a, Bernhardt and others 2002, Mulholland 2004,
13 Bernhardt and others 2005). All four streams demonstrated uptake of $\text{NO}_3\text{-N}$ over the reaches
14 studied, despite evidence of nitrification in benthic sediments at two of the sites. Day-night
15 differences in $\text{NO}_3\text{-N}$ uptake of stream reaches as well as isolated benthic sediments support the
16 conclusions of Webster et al. (2003) and Hall and Tank (2003) that differences in nutrient
17 spiraling are linked to metabolic activity. Differences in the relationship between stream
18 metabolism and nutrient uptake stem in part from the relative availability of autochthonous
19 versus allochthonous carbon sources, which in turn is influenced by interaction of the stream and
20 its catchment. Valett et al. (2002) proposed that streams at the two ends of this spectrum, desert
21 and forest streams, exhibit very different nutrient retention over successional time. Nutrient
22 retention in desert streams is dominated by autochthonous processes, and is therefore controlled
23 by the successional stage of in-stream autotrophs (e.g., following floods, Grimm 1987).

Conversely, the status of the catchment vegetation (seasonally as well as over successional time) controls retention in forest streams, where retention is dominated by processes fuelled by allochthonous carbon. Our findings suggest that with respect to NO₃-N uptake, autochthonous processes can play an important role in uptake even in forest streams where they contribute a relatively small portion of the carbon budget.

1 Table 2. Hydrologic and other physical characteristics of the four study streams. Values are obtained from field measurements and
2 tracer analysis. Reach lengths are given for both whole-stream metabolism and NO₃-N uptake measurements. With the exception of
3 width and depth, data are means $\pm$ standard errors from multiple solute additions (RC and GC, n = 6; EFWB and HWC, n = 4).
4 Within-site day and night means for discharge, temperature, and background NO₃-N concentrations were not significantly different (t-
5 test, p > 0.05; day and night means $\pm$ standard errors are given below overall mean values; day and night each represent half of the
6 solute additions). Channel width is the mean $\pm$ standard error for measurements taken along the study reach and depth was derived for
7 each injection from information on discharge, velocity and width (with the exception of HWC, see text).

	RC	GC	EFWB	HWC
	22-23 July	29-30 July	3-4 August	10-11 August
metabolism reach length (NO ₃ -N uptake reach) (m)	73.6 (73.9)	29.0 (18.8)	52.0 (52.0)	37.2 (23.3)

1 Table 3. Whole-system metabolism, NO₃-N uptake, and related variables for the four study streams. Photosynthetically active
2 radiation (PAR) is presented as photon flux density, a cumulative measure of light availability over the course of metabolism
3 measurements at each site. Metabolic measures are daily values derived from single (RC & GC) whole-stream measurements or are
4 averaged (EFWB & HWC) over two 24-hr periods. Uptake velocity and rate data are means $\pm$ standard errors for all solute additions
5 at each site (RC and GC, n = 6; EFWB and HWC, n = 4). Site mean values of NO₃-N uptake metrics with different superscripts are
6 significantly different (ANOVA, Tukey p<0.05).

	RC	GC	EFWB	HWC
PAR (mol m ⁻² d ⁻¹)	20.0	13.6	2.2	0.1

Benthic chamber uptake rate (µg NO ₃ -N m ⁻² hr ⁻¹)	1723 (110%)	-20 (-19%)	1067 (-101%)	240 (-70%)

3

Figure 1. Comparison of light and dark $\text{NO}_3\text{-N}$ uptake within each study stream. Open symbols represent the mean value obtained from daytime solute additions or benthic chamber incubations under light conditions and solid symbols represent mean values for night time additions or dark benthic chamber incubations ($n = 3$ for RC and GC; $n = 2$ for EFWB and HWC for daytime and night time solute injections; $n = 4$ for RC and EFWB, $n = 3$ for HWC, and $n = 2$ for GC for light and dark benthic chamber incubations). Error bars represent the standard error of the mean. Daytime whole-stream $\text{NO}_3\text{-N}$ uptake was not significantly greater than nighttime uptake (v_f or U greater; $p < 0.05$, one-sided t-test), whereas benthic uptake under light conditions was significantly greater than under dark conditions at 3 sites (indicated with an *; $p < 0.05$, one-sided t-test).

Figure 2. Relationships between $\text{NO}_3\text{-N}$ uptake and metabolism. Linear regression analysis was used to examine the relationships between $\text{NO}_3\text{-N}$ uptake and corresponding values of GPP and R for both whole-stream and benthic chamber measurements. Values of whole-stream $\text{NO}_3\text{-N}$ uptake (v_f and U) are from individual solute additions conducted during day (open symbols) or night (closed symbols). Whole-stream metabolism measures reflect average DO flux during the period in which solute additions were conducted (generally 1 to 2 hours). For benthic chambers, light (open symbols) and dark (closed symbols) rates of uptake were obtained and paired with rates of metabolism from the same chamber. Values from all sites were analyzed together (solid regression lines), and for relationships with GPP, additional regressions were conducted using only the values from the two sites with substantial autochthonous production (RC and GC; dashed regression lines). Only relationships significant at the $p < 0.05$ level are shown. Symbols are as follows: circle = East Fork of Walker Branch, triangle = Gallina Creek, square = Hugh White Creek, and diamond = Rio Calaveras.

Figure 3. Comparison of area-specific $\text{NO}_3\text{-N}$ uptake rates to calculated photoautotrophic assimilatory N demand. Rates of net primary production from whole-stream (closed symbols) and benthic chamber (open symbols) measurements were used along with a C:N molar ratio of 12:1 to calculate predicted algal N assimilatory demand (straight line represents the 1:1 line for measured:calculated values; see text for more details). Symbol shapes are as in Figure 2.
