On the Fluctuation Theorem for the Dissipation Function
and its connection with Response Theory

Abstract

Recently there has been considerable interest in the Fluctuation Theorem (FT). The Evans-Searles FT shows how time reversible microscopic dynamics leads to irreversible macroscopic behavior as the system size or observation time increases. We show that the argument of this FT, the dissipation function, plays a central role in nonlinear response theory and derive the Dissipation Theorem, giving exact relations for nonlinear response of classical N-body systems that are more widely applicable than previous expressions. These expressions should be verifiable experimentally. When linearized they reduce to the well known Green-Kubo expressions for linear response.
I. INTRODUCTION

Recently there has been considerable interest in a group of theorems known collectively as the Fluctuation Theorem (FT). Various forms of this theorem have been confirmed experimentally.¹ The FT is remarkable in that it represents one of the few exact results that apply to nonequilibrium systems far from equilibrium. It has been shown that in the weak field limit the Evans-Searles FT can be used to prove the well known Green-Kubo expressions for the linear response of thermostatted systems to an applied dissipative field.² For technical reasons the connection between response theory and the FT for deterministic systems, has been restricted to the linear regime close to equilibrium. Gavin Crooks³ has given a description of the connection between various stochastic versions of the fluctuation theorem and the so-called Kawasaki expression for the nonlinear response. However even in the stochastic case this connection did not extend to the more useful Transient Time Correlation Function (TTCF) formalism for the nonlinear response.⁴ In the present paper we give the first proof that thermostatted nonlinear response theory (both Kawasaki and TTCF) can be derived directly using the Evans-Searles Fluctuation function for classical systems satisfying time reversible deterministic dynamics. In fact the new derivation shows that the formal expressions for the unnatural homogenously thermostatted nonlinear response that have been derived in the past do in fact also formally apply much more generally, including to naturally thermostatted systems as occur in real experimental systems.

In Section II we will present general equations of motion for the deterministic and reversible nonequilibrium, thermostatted dynamics and discuss the use of thermostats. We also show how the N-particle distribution function and phase variables evolve under these dynamics. In Section III we present the Evans-Searles Transient FT (TFT) and discuss some of its important implications. Section IV presents the main results of this paper: the
II. THERMOSTATTED, NONEQUILIBRIUM DYNAMICS

Consider a classical system of N interacting particles in a volume V. The microscopic state of the system is represented by a phase space vector of the coordinates and momenta of all the particles, in phase space - \( \{q_1, q_2, \ldots, q_N, p_1, \ldots, p_N\} \equiv \{\mathbf{q}, \mathbf{p}\} \equiv \Gamma \) where \( q_i, p_i \) are the position and momentum of particle i. Initially (at \( t = 0 \)), the microstates of the system are distributed according to a normalized probability distribution function \( f(\Gamma, 0) \). While the results in this paper are generally applicable, to demonstrate its application to realistic systems, we separate the N particle system into a system of interest and a reservoir region containing \( N_w \) particles. We shall assume that the reservoir region contains many more particles than the system of interest, \( N_w \gg (N - N_w) \), and we write the equations of motion for the composite N-particle system, as,

\[
\begin{align*}
\dot{q}_i &= \frac{p_i}{m} + C_i(\Gamma) \cdot F_e \\
\dot{p}_i &= F_i(q) + D_i(\Gamma) \cdot F_e - S_i(\Gamma) \cdot p_i
\end{align*}
\] (1)

where \( F_e \) is the dissipative external field that couples to the system via the phase functions \( C_i(\Gamma) \) and \( D_i(\Gamma) \), \( F_i(q) = -\frac{\partial \Phi(q)}{\partial q_i} \) is the interatomic force on particle i, and \( \Phi(q) \) is the interparticle potential energy and the last term \( -S_i(\Gamma) \cdot p_i \) is a deterministic time reversible thermostat used to add or remove heat from the particles in the reservoir region.\(^{5,7}\) We assume that in the absence of the thermostatting terms the adiabatic equations of motion preserve the phase space volume, \( \langle \partial / \partial \Gamma \rangle \cdot \dot{\Gamma}^{\text{ad}} = 0 \): a condition known as the adiabatic incompressibility of the distribution function.
phase space, or $\text{AI}^5$. The thermostat multiplier can be chosen in a number of ways, such as using Gauss’ Principle of Least Constraint,\(^5\)\(^-\)\(^7\) to fix some thermodynamic constraint (e.g. temperature or energy). The thermostat employs a switch, $S_i$, which controls how many and which particles are thermostatted, $S_i = 0; \quad 1 < i < (N - N_{\text{therm}})$

$S_i = 1; (N - N_{\text{therm}} + 1) \leq i \leq N, N_{\text{therm}} \leq N_w$. The equations of motion for the particles in the system of interest are quite natural. The reservoir region is assumed to not interact with the dissipative field $\mathbf{C}_i, \mathbf{D}_i = 0; (N - N_w + 1) \leq i \leq N$ and the equations of motion for the more distant reservoir particles, $N_w < N_{\text{therm}} \leq i \leq N$, are supplemented with the unnatural thermostat term. It is worth pointing out that as described, equations (1) are time reversible and heat can be either absorbed or given out by the thermostat. This construction has been applied in various studies (see, for example references 8-10.). Of course, if $S_i = 1$ for all $i$, we obtain a homogeneously thermostatted system that has been studied in detail in the past.\(^5\)

One should not confuse a real thermostat composed of a very large (in principle, infinite) number of particles with the purely mathematical - albeit convenient - term $\alpha$. In writing (1) it is assumed that the reservoir momenta $\mathbf{p}_i$ are peculiar (i.e. measured relative to the local streaming velocity of the fluid or wall). When a Gaussian thermostat is used the thermostat multiplier is chosen to fix the peculiar kinetic energy of the wall particles

$$K_{\text{therm}} \equiv \sum_{S_i=1} p_i^2 / 2m = (d_c N_{\text{therm}} - 1) k_B T_w / 2. \quad (2)$$

with $N_{\text{therm}} = \sum S_i$. The quantity $T_w$ defined by this relation is called the kinetic temperature of the wall, and $d_c$ is the Cartesian dimension of the system. It is assumed that
\[ N_w, N_{\text{therm}} \gg (N - N_{\text{therm}}) > (N - N_w) \]. This means that the entire wall region can be assumed to be arbitrarily close to equilibrium at the thermodynamic temperature \( T_w \).

One might object that our analysis is compromised by our use of these artificial (time reversible) thermostats. However, the artificial thermostat region can be made arbitrarily remote from the system of interest by ensuring that the particles with \( S_i = 1 \) are far from the system of interest.\(^8,9,11\) If this is the case, the system cannot ‘know’ the precise details of how heat was removed at such a remote distance. This means that the results obtained for the system using our simple mathematical thermostat must be the same as those we would infer for the same system surrounded (at a distance) by a real physical thermostat (say with a huge heat capacity). This mathematical thermostat may be unrealistic, however in the final analysis it is a very convenient but ultimately irrelevant device.\(^9\)

As Tolman\(^12\) pointed out, in a purely Hamiltonian system, the neglect of ‘irrelevant’ degrees of freedom (as in thermostats or by neglecting solvent degrees of freedom in a colloidal or Brownian system) will inevitably result in a non-conservation of phase space volume for the remaining ‘relevant’ degrees of freedom. For a mathematical proof that when the thermostatting region has a much larger number of degrees of freedom than the unthermostatted system of interest, the Fluctuation Theorem is independent of the mathematical details of how the thermostatting is accomplished.\(^9\) This proof is given for an infinite family of so-called \( \mu \)-thermostats.

The exact equation of motion for the \( N \)-particle distribution function is the time reversible Liouville equation,\(^5\)

\[
\frac{\partial f(\Gamma, t)}{\partial t} = - \frac{\partial}{\partial \Gamma} [i \tilde{f}(\Gamma, t)] \equiv -iL(\Gamma)f(\Gamma, t)
\] (3)
where \( iL(\Gamma) \) is the distribution function (or \( f \)-) Liouvillean and appears in the propagator for the phase space distribution function \( f(\Gamma, t) = \exp(-iL(\Gamma)t)f(\Gamma, 0) \). The Liouville equation can also be written in Lagrangian form,\(^{13}\)

\[
\frac{df(\Gamma, t)}{dt} = -f(\Gamma, t) \frac{d}{d\Gamma} \Gamma \equiv -\Lambda(\Gamma)f(\Gamma, t). \tag{4}
\]

The presence of the thermostat is reflected in the phase space expansion factor,

\( \Lambda(\Gamma) \equiv \frac{\partial}{\partial \Gamma} \cdot \Gamma \), which is, assuming \( \text{AI} \Gamma \), to first order in \( N_{\text{therm}} \), \( \Lambda = -dc_{\text{therm}} \alpha \). The equation of motion for an arbitrary phase function \( B(\Gamma) \), is\(^5\)

\[
\dot{B}(\Gamma) = \Gamma \cdot \frac{dB}{d\Gamma} \equiv iL(\Gamma)B(\Gamma). \tag{5}
\]

where \( iL(\Gamma) \) is the phase variable (or \( p \)-) Liouvillean and appears in the propagator for phase variables \( B(\Gamma(t)) = \exp(iL(\Gamma)t)B(\Gamma(0)) \). The difference between the \( f \)-Liouvillean and the \( p \)-Liouvillean is, \( iL(\Gamma) - iL(\Gamma) = \Lambda(\Gamma) \). The time-reversibility condition implies that there exists a time reversal mapping, \( M^T \) such that \( \Gamma = M^T \exp(iLt)M^T \exp(iLt)\Gamma \), and this imposes some conditions on \( C_i(\Gamma) \) and \( D_i(\Gamma) \) in (1), that depend on \( M^T \).

### III. THE TRANSIENT FLUCTUATION THEOREM

Derivation of the Evans-Searles TFT considers the response of a system that is initially at equilibrium to application of a field. The initial distribution can be written in a quite arbitrary form,
\[ f(\Gamma, 0) = \frac{\exp[-F(\Gamma)]}{\int d\Gamma \exp[-F(\Gamma)]}, \quad (6) \]

where \( F(\Gamma) \) is some arbitrary single valued real function for which \( f(\Gamma, 0) = f(M^T \Gamma, 0) \). The Evans-Searles TFT\(^{13-16} \) states that provided the system satisfies the condition of ergodic consistency,\(^{15} \) the dissipation function \( \Omega(\Gamma) \), defined as\(^{15,16} \):

\[
\int_0^t ds \, \Omega(\Gamma(s)) \equiv \ln \left( \frac{f(\Gamma(0), 0)}{f(\Gamma(t), 0)} \right) - \int_0^t \Lambda(\Gamma(s))ds \\
\equiv \tilde{\Omega}_t \quad (7)
\]

satisfies the following time reversal symmetry\(^{13-15} \):

\[
\frac{p(\tilde{\Omega}_t = A)}{p(\tilde{\Omega}_t = -A)} = \exp[At]. \quad (8)
\]

The derivation of the TFT is straightforward and it has been given in the past (see for example, reference 15) and therefore will not be repeated here. The instantaneous dissipation function can be determined by differentiation of (7) as

\[
\Omega(\Gamma) = - \frac{\partial}{\partial \Gamma} \cdot \dot{\Gamma}(\Gamma) - \frac{\dot{\Gamma}(\Gamma)}{f(\Gamma, 0)} \frac{\partial}{\partial \Gamma} f(\Gamma, 0) \\
= - \frac{\partial}{\partial \Gamma} \cdot \dot{\Gamma}(\Gamma) - \dot{\Gamma}(\Gamma) \frac{\partial}{\partial \Gamma} \ln f(\Gamma, 0) \quad (9)
\]
and therefore $\Omega(\Gamma)f(\Gamma,0) = -\frac{\partial}{\partial \Gamma}(\tilde{\Gamma}(\Gamma)f(\Gamma,0))$, the divergence of $\tilde{\Gamma}(\Gamma)f(\Gamma,0)$ (i.e. the
dissipation function weighted by the initial distribution is the weighted divergence of the
phase space flow field).

It is very important to remember that the existence of the dissipation function $\Omega(\Gamma)$
at a phase point $\Gamma$, requires that $f(\Gamma,0) \neq 0$. The existence of the integrated form of the
dissipation function requires that the dynamics is ergodically consistent (i.e.
$\forall \Gamma, t \ s t f(\Gamma,0) \neq 0, f(\Gamma(t),0) \neq 0$). There are systems that fail to satisfy this condition. For
example, if we let the initial distribution be microcanonical and further assume that the
dynamics does not preserve the energy (there may be no thermostat or the thermostat may fix
the kinetic temperature or so), then ergodic consistency obviously breaks down. The existence
of the dissipation function (7) only requires that the initial distribution is normalizable and that
ergodic consistency holds. To prove the Evans-Searles Fluctuation Theorem requires an
additional condition: namely that the dynamics must be time reversal symmetric.

The TFT has generated much interest, as it shows how irreversibility emerges from
the deterministic, reversible equations of motion$^{17}$, and is valid arbitrarily far from
equilibrium. It provides a generalized form of the 2nd Law of Thermodynamics that can be
applied to small systems observed for short periods of time. It also resolves the longstanding
Loschmidt Paradox. The TFT has been verified experimentally.$^{1}$

The form of the above equation applies to any valid ensemble/dynamics combination,
provided the distribution function is invariant with respect to time reversal. However the
precise expression for $\Omega_t$ given in (7) is dependent on both the initial distribution and the
dynamics. This result is extremely general. It is valid arbitrarily far from equilibrium. It
leads to a number of other simple but important corollaries such as the Second Law
Inequality,$^{18}$
\[ \langle \Omega \rangle_{F_e, f(\Gamma,0)} \geq 0, \quad \forall t, F_e, f(\Gamma,0) \quad (10) \]

and the NonEquilibrium Partition Identity,

\[ \exp \left\{ -\Omega t \right\}_{F_e, f(\Gamma,0)} = 1, \quad \forall t, F_e, f(\Gamma,0) \quad (11) \]

The notation \( \langle \cdots \rangle_{F_e, f(\Gamma,0)} \) implies that the ensemble average is take over the ensemble defined by the initial distribution \( f(\Gamma,0) \) (6), with any value (including zero) for the external field \( F_e \) in the equations of motion.
IV. THE DISSIPATION THEOREM

We now derive the Dissipation Theorem, which shows that, as well as being the subject of the TFT, the dissipation function is also the central argument of both linear (i.e. Green-Kubo theory) and nonlinear response theory.

Firstly we note the Dyson Identity for two operators A, B

\[ \exp[(A + B)t] = \exp[At] + \int_0^t ds \exp[As]B\exp[(A + B)(t - s)]. \]  

(12)

To prove this identity we note that at \( t = 0 \) it is clearly true and for \( t > 0 \), the left hand side and the right hand side satisfy the same first order differential equation. Substituting \( A = -iL(\Gamma) \), and \( B = -\Lambda \) we find that,

\[ \exp[-(iL)t] = \exp[-(iL + \Lambda)t] = \exp[-iLt] - \int_0^t ds \exp[-iLs]\Lambda\exp[-(iL)(t - s)]. \]  

(13)

Recursive substitution and summing the resultant infinite series gives,

\[ f(\Gamma, t) = \exp[- \int_0^t ds \Lambda(-s)]\exp[-iL(\Gamma)t]f(\Gamma, 0) \]

\[ = \exp[- \int_0^t ds \Lambda(-s)]\exp[-F(\Gamma(-t)) + F(\Gamma(0))]f(\Gamma, 0). \]  

(14)

Comparing this with equation (7) we see that

\[ f(\Gamma, t) = \exp[- \int_0^t ds \Omega(\Gamma(s))]f(\Gamma, 0). \]  

(15)
Thus the propagator for the N-particle distribution function $\exp[-iL(\Gamma)t]$, has a very simple relation to exponential time integral of the dissipation function. As shown below, in the case of isokinetic nonequilibrium dynamics, this equation reduces to equation (7.2.17) of reference 5. In the case of adiabatic (i.e. unthermostatted) dynamics for an ensemble that is initially a canonical ensemble, this result is equivalent to (7.2.8) of reference 5, which is the distribution function derived by Yamada and Kawasaki\(^{20}\). However (15) is much more general and, like the TFT, can be applied to any initial ensemble and any time reversible, and possibly thermostatted dynamics that satisfies $A_\Gamma$.

From equation (15) we can calculate nonequilibrium ensemble averages in the Schrödinger representation

$$\langle B(t) \rangle_{E,t(\Gamma,0)} = \left. \langle B(0) \exp[-\int_0^t ds \Omega(\Gamma(s))] \rangle \right|_{E,t(\Gamma,0)}, \quad (16)$$

and by differentiating and integrating (14) with respect to time, we can write the averages in the Heisenberg representation as

$$\langle B(t) \rangle_{E,t(\Gamma,0)} = \int_0^t ds \left\langle \Omega(0) B(s) \right\rangle |_{E,t(\Gamma,0)}, \quad (17)$$

Equations (15-17) are new results. On both sides of equations (15-17) the time evolution is governed by the field dependent thermostatted equations of motion (1). The derivation of (16) and (17) from the definition of the dissipation function (7), is called the Dissipation Theorem. This Theorem is extremely general, and allows the determination of the ensemble average of an arbitrary phase variable under very general conditions. Like the FT it is valid arbitrarily far from equilibrium. As in the derivation of the FT the only unphysical terms in the derivation
are the thermostatting terms within the wall region. However, because these thermostatting particles can be moved arbitrarily far from the system of interest, the precise mathematical details of the thermostat are unimportant. Since the number of degrees of freedom in the reservoir is assumed to be much larger than that of the system of interest, the reservoir can always be assumed to be in thermodynamic equilibrium. There is therefore no difficulty in defining the thermodynamic temperature of the walls. This is in marked contrast with the system of interest, which may be very far from equilibrium where the thermodynamic temperature cannot be defined.

For the special case of isokinetic dynamics where the kinetic energy $K_{\text{therm}}(\Gamma)$ of the thermostatted particles is fixed and if the initial distribution is isokinetic

$$f(\Gamma, 0) \equiv f_k(\Gamma, 0) = \frac{\delta(2K_{\text{therm}} - (d_c N_{\text{therm}} - 1)k_B T_W) \exp[-\beta H_0(\Gamma)]}{\int d\Gamma \, \delta(2K_{\text{therm}} - (d_c N_{\text{therm}} - 1)k_B T_W) \exp[-\beta H_0(\Gamma)]}, \quad (18)$$

$H_0(\Gamma)$ is the internal energy of the entire system, and $\beta = 1/(k_B T_W)$, it is straightforward\textsuperscript{15,21} to show that the dissipation function is related to the generalized entropy production $\Sigma(\Gamma)$,

$$\Omega(\Gamma) \equiv \Sigma(\Gamma) = -\beta J(\Gamma) V \cdot F_e. \quad (19)$$

Here $V$ is the volume of the system of interest and $J(\Gamma)$ is the dissipative flux in the system of interest,

$$J(\Gamma) V \cdot F_e = -\sum_{i=1}^{N-N_0} \left[ \frac{p_i}{m} \cdot d_i - F_i \cdot c_i \right] \cdot F_e$$ \quad (20)$$
Although here we assumed a special dynamics where the kinetic energy of the thermostatted particles is fixed, the form of (19) must be true for other “thermostatted” dynamics (e.g. Nose-Hoover or constant energy etc.). Furthermore, if the reservoir region does not directly interact with the field, and $N_{therm}$ is large, and much larger than the number of degrees of freedom in the system of interest, the form of (19) is true in general (e.g. for thermostats where higher order moments of the momenta are constrained, stochastic thermostats etc.)

The dissipative flux, volume and field are properties of the system of interest and the only relevant property taken from the thermostatted region is its temperature.

Equation (17) can be written as the Transient Time Correlation function expression, for the thermostatted nonlinear response of the phase variable $B$ to the dissipative field $F_e$.

$$\langle B(t) \rangle_{\Gamma, F_e, 0} = -\beta V \int_0^t ds \langle J(0)B(s) \rangle_{\Gamma, \gamma} \cdot F_e.$$  \hspace{1cm} (21)

In the weak field limit this reduces to the well known Green-Kubo expression for the linear response

$$\lim_{F_e \to 0} \langle B(t) \rangle_{\Gamma, F_e, 0} = -\beta V \int_0^t ds \langle J(0)B(s) \rangle_{\Gamma, 0} \cdot F_e.$$  \hspace{1cm} (22)

where the right hand side is given by the integral of an *equilibrium* (ie $F_e = 0$) time correlation function. Equation (19) is not new, and equations (21, 22) have been known for many years. However, this interpretation referring to the separation of the properties of the system of interest from those of the thermostatting region (i.e. the gedanken experiment) is new.
It is interesting to compare a number of different relationships between the distribution function, the dissipation function and the phase space expansion factor. The first such relation is equation (15) above. We note that although the time argument in (15) is negative, the dynamics must still be governed by the field dependent, thermostatted equations of motion (1). Rewriting (7) we have

\[ f(\Gamma(t),0) = \exp[-\int_0^1 ds \Omega(\Gamma(s)) + \Lambda(\Gamma(s))]f(\Gamma(0),0). \] (23)

In a nonequilibrium steady state (SS), \( \langle \Omega(t) \rangle_{ss} = -\langle \Lambda(t) \rangle_{ss} \). We also note that if the initial ensemble is microcanonical (has a uniform density) and the dynamics is such that the total energy (system of interest plus walls and thermostat) is constant, then \( \Omega(t) = -\Lambda(t), \forall t \). Lastly we have the formal solution of the Liouville equation in its Lagrangian form (4),

\[ f(\Gamma(t),t) = \exp[-\int_0^t ds \Lambda(\Gamma(s))]f(\Gamma(0),0). \] (24)

Rather obviously the results of the Dissipation Theorem (17) can also be used to obtain a Fluctuation Dissipation Theorem as described in reference 22 by considering the case where the phase function \( B(\Gamma) = J(\Gamma) \). Furthermore, following reference 22 we find that when the equilibrium dissipative flux autocorrelation function is \( \delta \)-correlated,

\[ \langle J(t_1)J(t_2) \rangle_{E=0} = \langle J(t_1)J(t_2)\delta(t_2 - t_1) \rangle_{E=0}, \] and we obtain the fluctuation dissipation relation,

\[ \lim_{E \to 0} \langle J(t) \rangle_{E} = -\frac{1}{3} \beta V \langle J(0) \cdot J(0) \rangle_{E=0} \cdot F_e. \]
V. CONCLUSIONS

In this paper we have shown the central importance of the dissipation function to nonequilibrium statistical mechanics. It is the argument of both the FT and the Dissipation Theorem. These Theorems are both exact arbitrarily far from equilibrium. The FT has been confirmed in laboratory experiments\(^1\) and we see no reason why the Dissipation Theorem cannot be likewise tested in the laboratory.

Originally the dissipation function was defined in order to characterize the ratio of probabilities \(p_r\), of observing infinitesimal bundles of phase space trajectories originating \((t = 0)\) in a volume \(dV_\Gamma(0)\) to the probability of observing at \(t=0\), their time reversed antitrajectories \(dV_{\Gamma^*(0)}\), where \(\Gamma^*(0) \equiv M^T \Gamma(t)\),\(^{15}\)

\[
\frac{p_r(dV_\Gamma(0),0)}{p_r(dV_{\Gamma^*(0)},0)} = \exp[\int_0^t ds \Omega(\Gamma(s))]. \tag{25}
\]

Combining (25) with (15) shows that the nonequilibrium N-particle distribution function at time \(t\), can be written in terms of the ratio of probabilities of observing

\[
f(\Gamma(0),t) = \frac{p_r(dV_{M^T\Gamma(-t),0})}{p_r(dV_{\Gamma(0)},0)} f(\Gamma(0),0). \tag{26}
\]

We find it remarkable that the measure of irreversibility given in (25) by the dissipation function also features so centrally in the Dissipation Theorem. Our work shows that this measure of irreversibility is the prime function in determining how a nonequilibrium system will respond to a nonequilibrium perturbation or dissipative field.
We have given a derivation of the Dissipation Theorem (15-17) for an exceedingly
general set of time reversible equations of motion (1) and for an arbitrary initial distribution
\(f(\Gamma,0), (6)\). If one substitutes \(\Omega\) for \(B\) in equation (17) and then combines the resulting
equation with the Second Law Inequality (10), one can prove the following inequality for
integrals of transient correlations of the dissipation function,

\[
\int_0^t ds \langle \Omega(0)\Omega(s) \rangle_{F_e, f(\Gamma,0)} \geq 0, \quad \forall \ t, F_e, f(\Gamma,0). \tag{27}
\]

So, not only does the dissipation autocorrelation function start with a positive value, but for all
normalizable initial distributions and for any well defined dynamics with an arbitrarily strong
external field (if any) any negative tails in the transient correlation function \textit{cannot} be strong
enough for the integral (27) to ever become negative.

The Dissipation Theorem can be used to calculate the ensemble average of an
arbitrary phase variable and for arbitrarily strong dissipative fields, \(F_e\). In deriving (19) we
considered a system that preserves the initial (equilibrium) distribution in the absence of an
external dissipative field. Our formalism is sufficiently general to also describe the situation
where there is no external dissipative field \(F_e = 0\) but where dissipation still occurs because
the initial distribution is not preserved by the dynamics. The new results given in equations
(15-17) apply to this more general circumstance (this includes systems subject to rapid
temperature or pressure quenches etc, but in which there is no applied \textit{mechanical} dissipative
field).

We have argued that although the derivation employs unphysical thermostatting
terms, these are a convenient but ultimately irrelevant device. For both the Dissipation and
FT, dissipation takes place only in the system of interest (as measured by the dissipation
function) and on average, heat is lost to a surrounding reservoir region that is arbitrarily close to thermodynamic equilibrium at a known temperature.

Recently there have been a number of papers that have claimed that in some glassy systems, the fluctuation theorem and/or the fluctuation dissipation theorem “seems to fail”.23 We have a number of comments to make on this matter. Firstly if a mathematical theorem has been proved and the proof is correct (there are proofs of the theorems in question that are undoubtedly correct) then no experiment can prove that the theorem is incorrect. However, any mathematical theorem involves a set of conditions. It may well be that in certain situations the conditions required for the theorem to apply may not hold. In such a case the mathematical relation expected from the application of the theorem to the system being studied, may not be satisfied.

When people say that the Fluctuation Theorem or the Fluctuation Dissipation Theorem fails for glasses, they usually mean the relations obtained by applying these systems to a canonical distribution of states (ie the fluctuation relation equation (8) with equation (19) as the dissipation function etc.) With respect to linear response theory and the fluctuation dissipation theorem there are a number of necessary conditions for these theorems to apply. For equation (19) to apply these conditions include24:

1 the initial state must preserved by field-free dynamics (there cannot be any slow relaxation);

2 the initial distribution should be Boltzmann distributed at least over some ergodic subdomain of phase space;

3 if the phase space can be divided into distinct subdomains (as is natural in systems where multiple phases exist, glassy systems and where allotropes exist), the subdomains should be robust with respect to small changes in macroscopic conditions;

and, for linear response theory to apply
the applied fields need to be sufficiently weak that the system responds *linearly* with respect to field strength.

Recently we have shown that if one fixes the absolute magnitude of a constant driving force and one then lowers the temperature and approaches the glass transition, the reduced magnitude of the driving force (reduced in accord to the rapidly diverging response time of the system) increases without bound. In this case the expected linear response relation will fail because as the temperature is lowered at a fixed force value the system moves into the nonlinear response regime. For a detailed discussion of the application of the Transient Fluctuation Theorem to glassy systems see reference 24.

It has been proposed that in nonequilibrium systems the path integral of the entropy production should be an extremum (see, for example, reference 26). To leading order, close to equilibrium the dissipation function is the entropy production of linear irreversible thermodynamics, \( \sigma(t)V \cdot \lim_{F_e \to 0} (\Omega(t) - \sigma(t)V) = O(F_e^4) \). Our work shows that in natural systems that exchange heat with their surroundings, the maximum entropy production hypothesis, at best, can only be an approximation. In none of our expressions for the nonequilibrium N-particle distribution function (see equations (15), (23), (24)), is the probability density controlled *solely* by the path integral of the entropy production.

**ACKNOWLEDGEMENTS**

We would like to thank Lamberto Rondoni for his valuable comments on this work. We also thank the Australian Research Council for its support of this work.
REFERENCES

By time-reversible equations of motion we mean that there exists a time reversal mapping $M^T$ such that $\Gamma = M^T \exp(iLt)M^T \exp(iLt)\Gamma$.
