

Producers' Well-Being and Natural Resource Extraction: The Eaglewood Trade in Papua New Guinea

Nicolas Gerber and Anik Bhaduri

We illustrate how natural resource dependent and isolated communities manage their forest stock. Our model is based on field observations of the Eaglewood trade in Papua New Guinea. Using a dynamic model of household utility maximization and simulations, we analyze the impact of variations in the (monopsonistic) resource price on the households' consumption choices and their allocation of effort across depletive and nondepletive activities. The stock of forest is embedded directly in the households' utility function (existence value) and in their (nonseparable) production and consumption functions. We show that poverty (in production assets) does not inevitably lead to stock depletion.

Key Words: dynamic optimization, isolated communities, nonrenewable resource, producers' wellbeing

Over the last two decades, economists and political decision makers have increasingly raised questions related to the set of indicators they relied upon to measure economic performance and social progress. In particular, “[...] the notion of sustainable development has expanded to become an encompassing concept absorbing all dimensions of present and future economic, social and environmental well-being.” (Stiglitz et al. 2009, 57). Clearly, environmental conditions are part of the determinants of people's quality of life. Indeed, the idea of “greening” national accounts has been around for about two decades (e.g., Hamilton, 1994). Nonetheless, many issues remain unresolved in the actual integration of environmental goods and services in measures of economic development, which starts with national accounts (World Bank, 2010). As identified by Stiglitz et al. (2009), the interactions between the

sustainable use of natural resources, human well-being and development must be explicitly accounted. The concept of planetary boundaries, developed and described by Rockström et al. (2009), seems promising in that respect. However, as apparent in the literature reviewed below, in economic studies investigating the issue of the (sustainable) use of natural resource, particularly at household level, the notion of utility fails to account for what Stiglitz et al. (2009) name “[...] social and environmental well-being [...]”

One way to describe the interactions between sustainability, human well-being and development in a household model of natural resource use is to explore trade-offs between the household’s “love of nature” and its current period consumption of use benefits, as preserving nature inevitably implies to forego the consumption of certain benefits (e.g., firewood, groundwater,...). Krautkraemer (1985) considered the impact of amenity values (i.e., the “love of nature”), whose flow depend on the remaining stock of natural environment, on the optimal growth of a (nonrenewable) resource dependent economy. He shows that under certain conditions, a long term preservation of the environment can be optimal and depends on the initial endowments of capital and natural resource stocks. To the best of our knowledge, such an approach at the household level, where most effective resource use decisions are taken, is not covered in the literature. Pfaff et al. (2004) investigate the relationship between environmental degradation and poverty (the Environmental Kuznets Curve) with an analytical household utility model with consumption and amenity values. In their model households are pure consumers and the amenity value is derived from pure public goods.

Other studies investigate the relation between household or individual utility, poverty and the use of the natural resource base. In particular, Bulte and van Soest (1999, 2001) and Barbier (2010) model and investigate the impact of imperfect factor markets on the allocation of time (or labor) to resource depletive and nondepletive activities. Anthon et al. (2008) assess the impact of a tax on forest products on the depletive use of forests, using a similar approach of time allocation.

All these models consider household utility as a function of the consumption of market goods and leisure, as well as own-production in the case of Barbier (2010). Similar to Krautkraemer (1985), market consumption depends here (through an income constraint) on the resource stock. Yet Krautkraemer (1985) adds the amenity value of the resource stock as a direct determinant of the utility. Considering alternative activities or different consumption choices, whose utility does not depend on the resource stock, misses a crucial trade-off in the households’ optimization problem: depleting the resource stock impacts not only on the future income from resource-based activities (and this can increase or decrease income in a given period, depending on prices), but can be strictly utility decreasing. The love of nature takes a central role in the lifestyle and livelihoods of people and communities who are closely connected to the environment. Hence, modeling their behavior entails the direct incorporation of nature/environment in their utility function. For instance, such bonds can extend beyond typical benefits (wild foods, fresh water, raw materials,

energy, medicine,...) to include more “psychological” benefits in the form of cultural and spiritual values (Balmford et al. 2008).

Following a similar approach to Bulte and van Soest (2001), we present here an intertemporal model, with particular focus on the case of “economically isolated” communities depending on the natural resource base for their livelihoods. The economic isolation does not preclude the access to market goods, but crucially restricts the translation of surplus from natural resource exploitation into physical capital accumulation. Therefore, the total value of production and consumption, which includes utility drawn from their love of nature, are balanced in each period.

In the model, the households maximize the net present value of their own utility, which depends on the consumption of different types of goods. We categorize the goods as cash goods (rice, tinned fish, alcohol, etc.), bought on the distant markets, and traditional goods produced by the household itself. The latter are similar to the own production of farm households, with the exception that the goods can only be consumed by the household itself (i.e., no surplus sold on the market). However, in our model the stock of natural resource also enters directly the utility function, reflecting the idea of the “love of nature” and expanding the notion of well-being to social and environmental dimensions. Unlike Pfaff et al. (2008), this “amenity value” is not derived from the consumption of a public good and instead its value is directly related to the actions of the households. Further, the only option the households have to gain cash, and thus to consume market goods, is to extract forest products and sell them to exporting companies or their agents. This activity has two effects: it depletes the stock of forest resources and it consumes labor resources which otherwise could be allocated to traditional, nondepletive activities (e.g., pig hunting, fishing, and collecting fruits). Unlike Bulte and van Soest (2001), our producers only possessed their own labor at their disposal.

We analyze the model in terms of its equilibrium conditions and the impacts of price on the control and state variables (consumption and stock of forest) around the equilibrium, using comparative statics. The main findings of the paper are that in this setting, a decrease in price paid to the producers can induce a change in consumption choices as the marginal utility of marketed goods relative to the marginal utility of traditional goods decreases. Through a supply response mechanism, this can further lead to a decrease in resource extraction. The result, however, depends on the state of the resource stock. Hence, the case of a poverty-environmental degradation trap as described in Barbier (2010), resulting from a combination of poor access to capital and input markets and constrained income opportunities, will not necessarily unfold.

As suggested in the above, our model is generic to communities depending on natural resources and their own labor as their only assets. The model is specific in its treatment of the forest stock as a generic case of nonrenewable resource: as many of the communities’ activities (including harvesting the forest product being traded) depend on the fact that this is an old-growth forest, nonrenewable over a generation’s planning horizon and beyond. Indeed, we illustrate our

model using the case of forest communities in the northwestern provinces of Papua New Guinea (PNG). Without loss of generality, we introduce specific elements of market structure and pricing mechanisms to link the model with relevant policy elements. Traditionally hunters and gatherers, the communities of northwestern PNG have since the late 1990s benefited from the discovery of Eaglewood, a rare and valuable nontimber forest product. The discovery of Eaglewood in the region has opened up economic prospects for these communities, who until then were largely disconnected from any market.

Finally, we calibrate a simulation model based on data gathered during field work in 2002 and various data sets and literature gathered since. The simulations help us to understand the paths of key variables away from equilibrium and the direction of comparative effects (stock effects on production and utility, substitution and income effects in consumption patterns), thus enabling us to draw further conclusions on the environmental and well-being affects of price signals.

In the next section, we describe the particular setting in which we use our model, i.e., the production of Eaglewood in PNG. We describe the production process, the basic household economics and the structure of the Eaglewood trade in PNG. In Section 3 we present the model, its objectives and assumptions, as well as its theoretical analysis. Section 4 details the theoretical affects of price distortions on the resource owners' consumption patterns, and thus implicitly on the extraction rate of the natural resource. These results are supplemented by a closer look at the paths of key variables produced by a simulation model in Section 5. Finally, Section 6 concludes.

The Setting: The Eaglewood Trade in PNG

Eaglewood, or agarwood, is commonly known as *gaharu* in PNG. It is a heavy, resinous wood product resulting from the fungal contamination (mold) of specific species of trees in the *Aquilaria* and *Gyrinops* genera. Due to their rather small size, these trees hold no market value as timber. Eaglewood is a highly valuable product, traded and sold on markets in Southeast Asia, Hong Kong, and the Middle East in particular. Eaglewood and its derived products (e.g., Eaglewood oil) are treasured for their fragrance, used either as a luxury ambiance perfume or in religious ceremonies and traditional medicine. The size and shape of the hard resinous wood pieces also play a role in the price they command.¹ There is no consumption market for *gaharu* in PNG, which exports all of its production.

The extraction of *gaharu* in PNG only started in the late 1990s, as it was unknown to locals, and international traders were unaware of its existence under these longitudes. *Gaharu* is mostly found in the remote, often mountainous forests of PNG. Its extraction requires considerable effort: the

¹ For more information on Eaglewood trade, see Zich and Compton (2001) or Barden et al. (2000).

producers leave one of their settlements for a few weeks at a time,² making their way through thick forest until they find potential host trees. The process of extraction itself is guided by the few external signs associated with a good probability of finding gaharu inside the tree. Most of the time, the segment of the tree thought to be infected cannot be removed without cutting down the whole tree. This practice is not sustainable, decreases the prospect of future gaharu stocks and implies substantial damage to the forest directly around the tree. Yet for practical reasons, it is often not avoidable. Once the tree has been extracted, the gaharu is harvested by carving it out of the flesh of the tree. Pieces of gaharu typically weigh between a few grams to a few hundred grams; in rare cases it can go up to a couple of kilograms. The processing of gaharu does not take place in PNG (e.g., oil extraction, and sculptures), the resinous wood is sold soon to avoid any weight loss due to evaporation.

For the communities engaged in the extraction of gaharu in PNG, this represents a unique chance for cash income. During group interviews in seven villages of the East Sepik and Sandaun provinces, it was clearly expressed that income levels have risen significantly in those villages since the start of the gaharu trade. By 2003, this trade accounted for 70 percent up to 100 percent of their cash income.³

The market structure of gaharu trade in PNG is characterized by a large number of producers (hundreds of families harvest gaharu), whilst official records of exports show that only two export companies operated simultaneously (a third one was operating briefly in the early stages). Information about the quality of the gaharu, which can only be assessed post extraction, is strongly biased in favor of the traders: they have access to the international market, know how different characteristics besides oil content (approximated by density and weight) can affect prices and are the sole source of information for the forest owners. Between producers and traders in PNG, gaharu is priced per kilogram according to quality grades: Super-A, A, B, C and D.⁴

The gaharu trade in PNG remained unregulated until early 2002, when the government introduced a 10% ad valorem export tax. Based on the short time series at our disposal, which shows the total quantity and value of exports from PNG between 1999 and 2008, as well as the detailed export permits collected between 2002 and 2004, we observe a change in the composition of

² Traditionally hunters and gatherers, the clans and families typically move regularly between several villages and camps disseminated across their land.

³ The numbers are consistent with the statistics presented in Baxter (2001). However, even post gaharu trade, the producers remain in the low-range of rural annual incomes. The evidence collected during the interviews suggests that each family collected between 10 and 20 kg of gaharu per year between 2001 and 2003. Cross-checked with the annual official exports in Figure 1, this suggests that between 450 and 1200 families were active in the gaharu production during that period.

⁴ Indicative prices of gaharu qualities in PNG (as documented by the PNG Forest Authority in February 2002): Super A, 2000 PGK/kg; A, 1500 PGK/kg; B, 1000 PGK/kg; C, 500 PGK/kg; D, 50 PGK/kg. The US dollars per PNG Kinas (PGK) exchange rate was around 0.32 in 2005.

exports towards increased quantities of lesser grades and decreased quantities of higher grades (Figure 1). As higher grades command prices several orders of magnitude higher and no one except the traders can attest of the exact grade, this is hardly surprising. From a developmental and natural resource perspective, this tax evasion has implications for the producers: in offering lower grade prices for higher grade products, traders impact on the producers' supply and utility functions, as well as on the natural resource stock. We aim to capture such interactions and impacts in our model in the next section.

The Model

The objective of the model is to show how the direct utility of the stock of nature and depletive natural resource use can be balanced through the consumption choices of natural resource dependent communities. We illustrate and guide our model development based on our experience of the gaharu extraction and trade in PNG.

Without loss of generality, we simplify the setting by considering two grades for gaharu: high and low. They command prices p_h and p_l , respectively. We assume that gaharu, given its growth dependence on the natural conditions prevailing in an old-growth forest in PNG, is a nonrenewable resource over the people's planning horizon.⁵ Further, there is no opportunity to transform surpluses from natural resource use into capital, and their consumption expenditures are met through the revenue of gaharu sales in each period. The proportion of high-quality gaharu present in the forest is fixed and unobserved pre-harvest, and therefore dependent on the proportion of high-quality gaharu in the whole harvest. Finally, we assume that the decrease in the stock of old-growth forest mainly occurs from harvesting gaharu. The harvest of gaharu has a compound effect on the stock of forest, as the process entails the extraction of multiple surrounding trees.

The buyer, which we describe as a monopsonist, can "cheat" and purchase some of the high quality at the low price.⁶

The proportion of high quality in the forest (and in the extracted gaharu) is π , the proportion of low quality is $1 - \pi$ ($0 \leq \pi \leq 1$). The share of the high-quality harvest that the monopsonist purchases at p_l is α , the share of high quality harvest that he purchases at p_h is $1 - \alpha$ ($0 \leq \alpha \leq 1$). Given the total harvest q ,

⁵ Inoculation of the fungi takes place in agarwood plantations around the world for less than ten years, in India in particular. However, gaharu plantations are not yet practiced in PNG, where the transmission of the fungi to gaharu producing trees is nature's secret. Neighboring Indonesia was still conducting trial inoculations as late as 2011 (see Santoso et al. 2011).

⁶ The monopsony structure arises due to the information asymmetry about gaharu quality mentioned earlier, market access (producers have none) and also price collusion between the two exporters observed during field work. We encountered minimal illegal exports by producers during field work: for them this entails long and hazardous trips across the border to Indonesia.

Figure 1. Gaharu Exports in PNG, 1999–2008

Downloaded from <https://www.cambridge.org/core>. Griffith University, on 08 Aug 2017 at 00:44:24, subject to the Cambridge Core terms of use, available at <https://www.cambridge.org/core/terms>. <https://doi.org/10.1017/age.2016.33>

$(1 - \alpha)\pi q$ is the share of the total harvest that is purchased at high price, $(\alpha\pi + (1 - \pi))q$ is the share purchased at low price.⁷

The producer's objective function is:

$$\max U = \int_0^{\infty} u(x(t), c(t), s(t))e^{-rt} dt,$$

with N identical producers, each owning an identical share of the total resource privately, thus internalizing the effects of resource extraction on his or her share of the stock.⁸ Consumption enters the utility function as the consumption levels of two distinct classes of goods: the cash goods (c) can be bought on the market away from the village, and the traditional goods (x) are produced/exchanged or in any other way procured by undertaking traditional activities in and around the community. The different characteristics of these two groups of goods justify the need to keep them separate in the utility function, and emphasize the importance of traditional activities and goods to the local populations (e.g., the production of masks, of sago palm cake, or of "bush meat"). Substitution between the two classes of goods is calculated through the allocation of labor.⁹ Capital is absent from the objective function and from the rest of the model, because the producers have no means of substitution between capitals due to the "primitive" nature of the economy; everything in the model is determined by labor allocation, which is in turn is determined by the actions of the monopsonist.

The objective function is subject to the equation of motion of the state variable (stock),

$$(1) \quad \dot{s} = -mq(t),$$

with $q(t)$ the harvest in period t and m the strictly positive constant, denoting the impact on the stock of forest per harvested kilogram of gaharu. As mentioned above, gaharu grows in old-growth forests. Its growth rate, like the natural growth rate of the old-growth forest, is considered to be nil over the lifetime of the producers. Therefore, the stock of the forest is only a function of the harvest of gaharu (Conrad, 1999, Chap. 4.6).

The producers have a choice variable, the level of consumption of traditional goods, x , which is a vector of nonmarketed goods (including their leisure time), and a control variable, c , which represents their consumption vector of all

⁷ Our results would also hold by considering the average price received by the producers. Our setting describes in more details the impact of the monopsonist's decision on the producers' behavior.

⁸ This seems reasonable in PNG, where clans within the village traditionally own specific areas of the forest.

⁹ In Bulte and van Soest (2001) for instance, the labor constraint is substituted directly in the objective function. The substitution is then directly done over the different utility levels offered by combinations of consumption baskets.

marketed goods. As the only source of income available to the producer is the sale of gaharu, the total value of the marketed goods consumed in each period is constrained by the total value of gaharu sales in the same period. Thus,

$$(2) \quad c(t) = \frac{1}{p_c} (\pi(\alpha + 1)(p_l - p_h) + p_l)q(t) \\ = kq(t).$$

So the budget constraint above provides the link between the resource extraction and the consumption of cash goods.¹⁰ As we have one cash good (or class of goods, $c(t)$), its consumption is equal to a fixed proportion of the harvest, this proportion being a price ratio of the goods consumed and of the goods produced (qualities of gaharu). Naturally, the harvest function is also a function of the stock of the resource, $q(t) = q(s(t))$, so that $c(t)$ is an indirect function of the stock level. Production and consumption must be balanced in each period (as in Bulte and van Soest, 2001), because the goods x are not marketable, and the income derived from the production of c is not invested, but consumed. For this particular case of gaharu in PNG, this follows anecdotal evidence collected in the field¹¹ and further assumes that no cash resulting from the sale of gaharu is kept for future consumption.

By determining the amount of cash and traditional consumption, the producer determines the level of labor he invests into collecting gaharu or into traditional activities. The total labor (or time, or effort) available to the producer in each period, $l(t)$, is normalized to 1. Thus the substitution between x and c is constrained by the effort function:

$$l(x(t), c(t)) = 1.$$

The current value Hamiltonian for the optimal control problem of the producer is¹²

$$H_c(x, c, s, \lambda, \gamma; \alpha) = u(x, c, s) + \lambda \left[-\frac{1}{k}c \right] + \gamma[l(x, c) - 1].$$

The optimal conditions are:

1. $x(t)$ and $c(t)$ maximize $H_c(x, c, s, \lambda, \gamma; \alpha)$ for all t , so $\frac{\partial H_c}{\partial x} = 0$ and $\frac{\partial H_c}{\partial c} = 0$,
2. $\dot{\lambda} = r\lambda - \frac{\partial H_c}{\partial s} = f(s, \lambda)$,
3. $\dot{s} = -q(t)$,

¹⁰ Note that $k > 0$ by definition, as $c(t)$ cannot be negative.

¹¹ Examples include the expression "going to the ATM" (cash machine), in reference to taking trips into the forest to search for and extract gaharu.

¹² The time argument is dropped from this point on, whenever possible, to simplify the notation.

$$4. s(0) = s_0, \text{ and}$$

$$5. \lim_{t \rightarrow \infty} \lambda(t)e^{-rt} = 0.$$

Solving condition 1.:

$$(3) \quad \frac{\partial H_c}{\partial x} = u_x + \gamma l_x = 0$$

and

$$(4) \quad \frac{\partial H_c}{\partial c} = u_c - \lambda \frac{1}{k} + \gamma l_c = 0.$$

Solving condition 2.:

$$(5) \quad \begin{aligned} \dot{\lambda} &= r\lambda - \frac{\partial H_c}{\partial s} \\ &= \lambda \left(r + \frac{1}{k} c_s \right) - u_s. \end{aligned}$$

Combining equations 3 and 4 to eliminate γ , and isolating λ , we get

$$(6) \quad \lambda = k \left(u_c - u_x \frac{l_c}{l_x} \right).$$

As l_c is the increase in effort requirement caused by a marginal increase in the consumption of c (and similarly for x), l_c/l_x is the marginal rate of effort substitution (MRS), i.e., the rate at which effort is transferred from harvesting gaharu to undertaking traditional activities when a marginal quantity of x is substituted for a marginal quantity of c .

Differentiating equation 4 with respect to time gives

$$u_{cc}\dot{c} - \dot{\lambda} \frac{1}{k} = 0.$$

Isolating $\dot{\lambda}$ and equating to equation 5 leads to, after substituting λ by equation 6,

$$ku_{cc}\dot{c} = (u_c - u_x \text{MRS}) \left(r + \frac{1}{k} c_s \right) k - u_s.$$

From this equation, we derive that

$$(7) \quad \frac{\dot{c}}{c} = \left(\frac{u_c}{u_{cc}} \frac{1}{c} \right) \left[\left(1 - \frac{u_x}{u_c} MRS \right) \left(r + \frac{1}{k} c_s \right) - \frac{1}{k} \frac{u_s}{u_c} \right].$$

In order to have some intuitive interpretation of this equation, we assume a steady state equilibrium. This leads to

$$(8) \quad u_c - u_x MRS = \frac{u_s}{rk + c_s}.$$

This equation makes the link between the utility of consumption on the LHS and the stock management arguments on the RHS. It also gives indications on the different dynamics of our problem around the equilibrium. For instance, the RHS is different from zero provided that the producers care about nature (i.e., if $u_s > 0$). If the producers do not care about nature, then the only capital they can allocate is their labor endowment, and in this case $\frac{u_c}{u_x} = \frac{l_c}{l_x}$, meaning that the relative marginal utility of goods x and c is entirely driven by the labor allocation they imply. In the more general case where producers do care about nature: starting from the equilibrium, if the producers increasingly value nature, then the RHS increases (as u_s increases), and thus $\frac{u_c}{u_x} > \frac{l_c}{l_x}$. This in turn means that as the depletive activity is decreased, its marginal utility increases relative to the marginal utility of the nondepletive activity.

Formally, defining η as the constant elasticity of the marginal utility of c with respect to its level of consumption ($\eta < 0$), and rewriting equation 7, we get the following system of differential equations:

$$(9) \quad \begin{aligned} \dot{c} &= \frac{c}{\eta} \left[\left(u_c - u_x \frac{l_c}{l_x} \right) (rk + c_s) - u_s \right] \frac{1}{ku_c} \\ \dot{s} &= -\frac{1}{k} c. \end{aligned}$$

We can get the elements of J_E , the Jacobian matrix of the reduced linearized system (evaluated at the equilibrium). Defining $\dot{c} = f(c, s)$ and $\dot{s} = g(c, s)$,

$$J_E = \begin{vmatrix} f_c & f_s \\ g_c & g_s \end{vmatrix}.$$

The different elements of the Jacobian are:

$$f_c = \frac{1}{\eta} \frac{1}{k u_c} \left[\left\{ \left(u_c - u_x \frac{l_c}{l_x} \right) (rk + c_s) - u_s \right\} \left\{ 1 - \frac{c u_{cc}}{u_c} \right\} + c u_{cc} (rk + c_s) \right]$$

$$f_s = \frac{1}{\eta} \frac{c}{k u_c} \left[\left(u_c - u_x \frac{l_c}{l_x} \right) c_{ss} - u_{ss} \right]$$

$$g_c = -\frac{1}{k}$$

$$g_s = 0$$

such that the determinant of the Jacobian is

$$|J_E| = -\frac{1}{\eta} \frac{c}{k^2 u_c} \left[\left(u_c - u_x \frac{l_c}{l_x} \right) c_{ss} - u_{ss} \right],$$

while the trace of the Jacobian is $tr J_E = f_c$. The sign of the determinant $|J_E|$ is ruled by the expression in the square brackets, as the terms outside of them are positive. A negative determinant would ensure the equilibrium is a saddle point, whereas $|J_E| > 0$ could yield a stable or unstable equilibrium, depending on the sign of the trace.

The Impacts of Price Distortions

In this section, we investigate the impacts of the monopsonist’s distorted price signals (i.e., the “cheating” described earlier) on the producers’ consumption of market goods (i.e., the “developmental” impact).

Looking at the system (9), we start from the equilibrium, where $\dot{c} = 0$ and $\dot{s} = 0$. This yields the following:

$$\left(u_c - u_x \frac{l_c}{l_x} \right) (rk + c_s) - u_s = 0$$

$$(10) \quad -\frac{1}{k} c = 0.$$

Based on this system we can analyze the variations in consumption and natural resource stock around the equilibrium. We then take the total differential of each of these equations with respect to c , s and α . After rearranging, dividing through by $d\alpha$ and rewriting all remaining differentials as partial derivatives, we can organize the solution in the following matrix form:

$$(11) \quad \begin{vmatrix} u_{cc}(rk + c_s) & \left(u_c - u_x \frac{l_c}{l_x}\right) c_{ss} - u_{ss} \\ -\frac{1}{k} & -\frac{1}{k} c_s \end{vmatrix} \begin{vmatrix} \frac{\partial c}{\partial \alpha} \\ \frac{\partial s}{\partial \alpha} \end{vmatrix} = \begin{vmatrix} -\left(u_c - u_x \frac{l_c}{l_x}\right) rk' \\ -\frac{1}{k^2} k'c \end{vmatrix}.$$

We will then apply Cramer's rule to calculate the comparative static impacts of α on the extraction (through the impact on consumption c) and the stock. To that effect, we first calculate the determinant of M_E , the Jacobian matrix of the system (evaluated at the equilibrium):

$$|M_E| = -u_{cc}(rk + c_s) \frac{1}{k} c_s + \frac{1}{k} \left[\left(u_c - u_x \frac{l_c}{l_x}\right) c_{ss} - u_{ss} \right].$$

The sign of the determinant $|M_E|$ must be negative to ensure concavity and thus a maximum. This determines that the expression in the square brackets must be negative, a result which will be useful later on. Applying Cramer's rule, we get:

$$(12) \quad \frac{\partial c}{\partial \alpha} = \frac{\left(u_c - u_x \frac{l_c}{l_x}\right) rk' \frac{1}{k} c_s + \frac{1}{k^2} k'c \left[\left(u_c - u_x \frac{l_c}{l_x}\right) c_{ss} - u_{ss} \right]}{|M_E|}$$

Assuming a saddle point, and remembering that $|M_E| < 0$, we can see the following. As the second term of the numerator contains c it should dominate the first term of the numerator, which is negative, so that $\frac{\partial c}{\partial \alpha} < 0$: for stock levels below a critical value \bar{s} , the absolute value of the square brackets (which is determined by the second derivatives of c and u with respect to stock) is high enough so that in combination with the consumption level they dominate the numerator. If such is the case, an increase in the proportion of high-value gaharu paid at the low-grade price (α) leads to a reduction in the consumption level, through a decrease in the production of gaharu. For high values of the stock, i.e., $s > \bar{s}$, the second term of the numerator becomes very small (eventually tends to zero) as the second order derivatives c_{ss} and u_{ss} tend to zero themselves as $s \rightarrow \infty$. Thus, for $s > \bar{s}$ the first term in the numerator dominates and $\frac{\partial c}{\partial \alpha} > 0$.

Intuitively, these two results can be interpreted as follows: at stock levels below a critical stock \bar{s} , the opportunity cost of extracting more resource in terms of x and in terms of the producers' "love of nature" is prohibitively high (higher than the marginal benefit of increasing consumption c) and the producers substitute x for c , thus decreasing extraction. The "substitution effect" is stronger than the "income effect." When the stock is sufficiently

high, i.e., higher than \bar{S} , the inverse is true: as the opportunity cost of increasing extraction is low in terms of forest stock, more gaharu is extracted to compensate the lower prices, i.e., the “income effect” dominates the “substitution effect.”¹³

To formalize this discussion, we look into the impact of the stock s on $\frac{\partial c}{\partial \alpha}$. Renaming the numerator in equation 12 as A ,

$$(13) \quad \frac{\partial c}{\partial \alpha \partial s} = \frac{A_s |M_E| - |M_E|_s A}{|M_E|^2}.$$

The sign of this expression is determined by the numerator, as the denominator is by definition positive. Hence, we compute (keeping in mind that cross derivatives are all zero and further assuming that third level derivatives are also zero)

$$(14) \quad \begin{aligned} A_s |M_E| - |M_E|_s A &= \left[\left(u_c - u_x \frac{l_c}{l_x} \right) r k' \frac{1}{k} c_{ss} + \frac{1}{k^2} k' c_s Z \right] \\ &\quad \left[-u_{cc} (rk + c_s) \frac{1}{k} c_s + \frac{1}{k} Z \right] \\ &\quad - \left[\left(u_c - u_x \frac{l_c}{l_x} \right) r k' \frac{1}{k} c_s + \frac{1}{k^2} k' c_s Z \right] \\ &\quad \left[-u_{cc} (rk + c_s) \frac{1}{k} c_{ss} - u_{cc} c_{ss} \frac{1}{k} c_s \right] \\ &= \frac{k'}{k^2} \left[\begin{aligned} &-\frac{1}{k} u_{cc} (rk + c_s) Z (c_s^2 - c c_{ss}) \\ &+ \left(u_c - u_x \frac{l_c}{l_x} \right) r c_{ss} (Z + u_{cc} c_s^2) \\ &+ \frac{1}{k} c_s Z (Z + c c_{ss} u_{cc}) \end{aligned} \right] \\ &= \frac{k'}{k^2} [E + F + G] \end{aligned}$$

The term E is negative, F is positive, while G is negative (applying the logic that terms with c dominate terms counting only first and second order derivatives). As k' is negative, and applying the same logic (dominance of the magnitude of c

¹³ This is our interpretation of the results. We do not formally prove the existence of these two effects and their relative magnitudes.

over derivatives of c and u , i.e., the dominance of $E + G$ over F), we find that $\frac{\partial c}{\partial \alpha \partial s} > 0$. Two cases must be considered separately here:

- $\frac{\partial c}{\partial \alpha} < 0$: in this case ($s < \bar{S}$), a marginal increase in the stock level leading to an increase in $\frac{\partial c}{\partial \alpha}$ is interpreted as the negative relationship between c and α becoming less strong.
- $\frac{\partial c}{\partial \alpha} > 0$: in this case ($s > \bar{S}$), the positive relationship between c and α becomes stronger, producers will harvest increasing amounts of gaharu to compensate for the loss in revenue and to increase their consumption. Nonetheless, as $E + F + G \rightarrow 0$ as $s \rightarrow \infty$, the impact of a marginal change in stock on $\frac{\partial c}{\partial \alpha}$ vanishes (i.e., $\frac{\partial c}{\partial \alpha}$ remains constant). The maximum value by which a marginal change in α can increase c is equal to the sales value of harvesting out the remainder of the stock, which we call \bar{c} . Figure 2 gives a graphical interpretation of $\frac{\partial c}{\partial \alpha \partial s}$.

Simulations

In this section, with the help of numerical analysis, we attempt to show how the gaharu producers choose their path of wellbeing in terms of consumption of marketable and nonmarketable goods given different levels of cheating of the buyer. The monopsonist buyer in the model has the ability to deprive the gaharu producers by paying them the price for low quality gaharu to the high quality gaharu harvested by labelling the product wrongly. In the numerical analysis, we have considered three different scenarios with different levels of cheating (high, medium and low), which is defined as the ratio of high quality gaharu the monopsonist purchases as low quality to the total amount of high quality of gaharu actually produced. The harvest of gaharu trees is assumed to follow a Cobb-Douglas production function of stock and labor with its coefficients denoting the output elasticities of labor and stock. We have assumed two different stock effects (high and low), i.e., two different output elasticities of stock, to investigate how stock effects can influence the labor allocation and the consumption of marketable and non-marketable goods.¹⁴ Further, we assumed different functional forms for the utility function: an additively separable utility function and a "Cobb-Douglas" type of utility

¹⁴ From here onwards, by stock effect we refer only to the stock elasticity of gaharu production.

Figure 2. The Relationship Between s and $\partial c/\partial \alpha$

function, but we kept the parameter values constant across the different forms.¹⁵ Naturally, the two functional forms have different implications in terms of the marginal utilities of the goods c , x and the resource stock s : the separable form implies that these marginal utilities are strictly independent of the other variables, the “Cobb-Douglas” form allows for such interactions. In other words, under the separable utility function the consumption choice (between c and x) is made myopically with respect to its impact on resource depletion. We believe this is representative of the reality. As trade-offs exist, even if not acutely perceived by the gaharu producers, the resource stock indirectly affects consumption choices through the budget constraint. In the Cobb-Douglas utility function, the resource stock should affect consumption choices more directly, through the cross terms of the derivatives.

The parameter values, shown in Table 1 are intended to be representative of actual values. We have used the @ Risk software to simulate and optimize. Monte Carlo simulations account for risk in the model: we fit a probability distribution for the quantity and quality of gaharu in a given tree and let the

¹⁵ A “baseline” simulation with no cheating was also tested but is not presented, as the results are almost identical to the case with low cheating, the latter being more telling when comparing outcomes under different cheating levels.

Table 1. Simulations: Parameter Definitions and Values

Parameters	Values / Formulas
Discount factor (ρ)	0.95
Number of trees with Gaharu (mean = 500 and variance = 20)	500
Probability of harvest of high quality Gaharu (π)	0.01
Average price of high quality Gaharu (p_h) in USD/ton	600000
Average price of low quality Gaharu (p_l) in USD/ton	20000
Average price index of the market goods (p_c)	100
Probability of cheating (α) - low; medium; high	0.1;0.35;0.6
Amount of Gaharu per tree (θ) in tons per tree	0.0001
Forest stock elasticity of Ganaru harvest q (a) - low; high	0.1;0.7
Labor elasticity of Gaharu harvest q (b)	0.08
Harvest function of Gaharu trees (q)	$q = q(s, l) = s^a l^b$
Total Gaharu collected (g) in tons	$g = \theta q$
Gaharu sold as high quality (g_h) in tons	$g_h = (1 - \mu)\pi\theta q$
Gaharu sold as low quality (g_l) in tons	$g_l = g - g_h$
Consumption of marketable goods (c)	$c = \frac{(p_h g_h + p_l g_l)}{P_c}$
Consumption of nonmarketable (traditional) goods (x)	$x = (l)^\mu$
Labor elasticity of x (μ)	-0.1
Additive-Separable Utility function (u)	$u = (c - \bar{c})^\beta + (x - \bar{x})^\gamma + (s - \bar{s})^\delta$
Cobb-Douglas Utility function (u)	$u = (c - \bar{c})^\beta (x - \bar{x})^\gamma (s - \bar{s})^\delta$
Consumption (c) elasticity of u (β)	0.04
Consumption (x) elasticity of u (γ)	0.01
Stock (s) elasticity of u (δ)	0.01
Subsistence level of consumption of market goods (\bar{c})	10
Subsistence level of consumption of nonmarket goods (\bar{x})	1
Minimum level of forest stock (\bar{S}) in trees	500
Labor (l)	Choice variable
Stock of forest (s)	State variable
Initial stock of forest (s_0) in trees	25000

simulation runs converge to a most probable outcome after 1000 runs. The producers are maximizing the present discounted value of utility by choosing their labor allocation to gaharu production.¹⁶

We now compare changes in the decision variables of the producers (l , c , s and x) based on the change (increase) in the share of high quality gaharu purchased as low quality, from low to medium and from medium to high, referred to as low and high increase in cheating (α) respectively. We compare the results under these scenarios given low and high stock effects in Table 2, the “stock effect” referring to the impact of the stock of old-growth forest on gaharu production (parameter “ a ” in Table 1). The motivation for this comparison is that the stock effect appeared to be the most important parameter behind the simulation results, and we thus test for its impact on the results. We base this comparison on the percentage changes in the values assumed by the decisions variables in a given year, then take the average of these percentages over 50 years. The reason for using percentage changes is that they eliminate scaling effects in our simulations, which might distort the comparisons while merely reflecting the sometimes arbitrary nature of the choice of initial values of the decision variables, parameter values and measurement units. Taking the average value eliminates the random component embedded in the optimal value of the decision variables in any given period.

The results based on the additive utility function indicate that under a low stock effect of old-growth forest on the production of gaharu (i.e., a low stock effect “ a ” as defined in Table 1), an increase in the level of cheating by the monopsonist decreases the allocation of labor to gaharu production. This is irrespective of that change happening at the lower end of cheating ($\alpha = 0.2$ to $\alpha = 0.35$) or at the higher end ($\alpha = 0.35$ to $\alpha = 0.6$).¹⁷ So as the average price of gaharu decreases, the marginal utility of labor allocated to gaharu production decreases and labor is rather allocated to traditional activities. The rate of this reallocation increases on average for higher cheating ratios (−9% for the low-end increase, −16% for the high-end increase). The only other significant result is a 3% decrease in the consumption of market goods under the low increase in cheating. The decrease in consumption is due to the price effect (both income and substitution effect). These simulations do not pick up a significant impact of an increase in cheating on the decision variables under the low stock effect.¹⁸ It is hard to understand intuitively

¹⁶ This differs from the theoretical model. However, as the producers cannot save capital and production and consumption are equal in each period, choosing l or x (and c) is similar. In the context of the simulations, choosing l (by-passing the consumption choice in favor of the underlining choice of effort allocation) improved the traceability of the results and dictated our choice.

¹⁷ Note that the increments in cheating are almost the same in relative terms: +75% for low increase scenario ($\alpha = 0.2 \rightarrow 0.35$) and +71% for the high increase scenario ($\alpha = 0.35 \rightarrow 0.6$).

¹⁸ We have performed sensitivity analysis of our results in terms of their dependence on extreme values of year-on-year changes for all four decision variables: the signs and values of

Table 2. Impacts of Pricing on Labor, Consumption Types, and Resource Stock

Y	Stock Effect (α)	Change in α	Average Year-on-Year Changes in %			
			l	c	s	x
Additive Separable Utility Function	Low	Low increase	-9.37	-3.34	-0.01	-0.38
	Low	High increase	-16.22	-0.07	-0.00	0.66
	High	Low increase	84.33	-2.76	-2.80	-4.46
	High	High increase	53.33	-5.16	-6.22	-6.82
Cobb-Douglas Utility Function	Low	Low increase	35.95	-0.59	-0.03	-4.16
	Low	High increase	-25.11	-0.09	-0.01	4.24
	High	Low increase	37.50	-2.97	-2.85	-3.34
	High	High increase	65.93	-5.08	-5.26	-6.88

why a strong effect of decreased average prices on the allocation of effort or labor is transmitted neither to the stock nor to consumption (of market or nonmarket goods). Yet the fact is that with the average year on year changes close to zero for c , s and x , we cannot hypothesize on the relative sizes of the stock, income and substitution effects, we can only observe that their combined effect is close to zero. For instance, the stock may affect simultaneously harvest and thus cash income and consumption, the utility derived from traditional activities and goods, and the direct utility expressed as care for nature.

In the case of a high stock effect, we observe a direct impact of a decrease in average prices as an increase in the allocation of labor to gaharu production, at low and high levels of cheating. The increase in labor allocation is very substantial in both cases. It is interesting to see such a strong dichotomy of impact on labor allocation between the low and high stock effect scenarios, suggesting that policy instruments to regulate the gaharu activity (through price controls in particular) need to pay close attention to the driving factors of production efforts. Comparatively to the impact on labor, under the high stock effect the impacts on market consumption, stock and nonmarket goods are smaller, but consistently negative.¹⁹ Again, the cross-dynamics behind the changes in the decision variables are too complex to attempt to single out substitution, income and stock effects (on production and on well-being). It seems however that under this scenario, the stock effects dominate the

the average changes (%) are usually robust, except for these five values below 1%. In those cases, the absolute values are robust (always among the 0 and 1 % mark), but the sign can easily change; we consider them as "no impacts." The sensitivity check was performed by deleting the outlier value and re-running the simulation for that period.

¹⁹ In this case too, we performed sensitivity analyses. Both the signs and values of the percentage changes in the decisions variables were robust to the smoothing of extreme year-on-year changes.

combinations of substitution and income effects: more labor allocated to gaharu production does not translate into more real income (the consumption of market goods decreases). Naturally, as labor is diverted to gaharu production, the stock of forest and the consumption of traditional good and activities decrease.

Under the Cobb-Douglas utility function, an increase in cheating produces a decrease in labor allocation to gaharu production only at low stock effect and a high increase in cheating. In all other cases, decreased average prices for gaharu lead to more labor allocation to gaharu extraction, with the expected decreases (3 to 6%) in traditional consumption and in stock, but without increased consumption of market goods (dominance of the stock effect over the combined substitution and income effects, as discussed above). This further emphasizes the potential difficulty regulating the gaharu activity through price controls, as impacts on stock and well-being depend on the complex interactions of the stock income and substitution effects.

Finally, we also explore how the relationship between the consumption of market goods and the level of cheating is influenced by the stock level. In our theoretical model, by developing equation 13 we found that $\frac{\partial c}{\partial \alpha \partial s} > 0$, which can be interpreted in two ways: with $s < \bar{S}$, the negative relationship between c and α is less strong for higher stock levels or, with $s < \bar{S}$, the positive relationship between c and α is stronger for higher stock levels. Table 3 shows that under the additive utility function, a low stock effect weakens the negative relationship between the consumption of market goods and the increase in the level of cheating for higher stock levels, as predicted.²⁰ This is equivalent to our theoretical results for $s < \bar{S}$. We find similar results under the high stock effect scenario, so in our simulations it seems we are never above the critical stock as defined in our theoretical model. These results are rather robust to the definition of the “higher” or “lower” stock values.²¹ These observations broadly hold under the Cobb-Douglas utility function, except in the case of the low stock effect, low increase in cheating and high stock level. It seems that much of the labor reallocation towards gaharu that was observed in Table 2 under this scenario takes place when the stock level is high (i.e., in the earlier periods). This allows the income effect to dominate (and thus consumption to increase) momentarily, at the cost of accelerating

²⁰ We have defined “low” and “high” stock levels by calculating the year-on-year average changes over periods $t = [1, \dots, 25]$ and $t = [26, \dots, 50]$, respectively, following the logic that the stock levels decrease from t_1 to t_{50} .

²¹ For this sensitivity analysis, we used varied averages of the year-by-year changes in c , for increasing values of α : $t = [3, \dots, 23]$; $t = [24, \dots, 44]$, and $t = [1, \dots, 21]$; $t = [29, \dots, 49]$, and $t = [5, \dots, 20]$; $t = [30, \dots, 45]$, as comparison pairs of high-low stocks, deliver the same results as in Table 3 in terms of the sign and relative magnitudes of all the effects reported. The pair $t = [10, \dots, 20]$; $t = [30, \dots, 40]$ gives results difficult to interpret, which we attribute to the need to average across enough periods to decrease the weight of uncharacteristic results.

Table 3. Impacts of Stock Levels on Consumption

Utility Function	Change in α	Changes in the Consumption of Market Goods (c), %			
		Low Stock Effect (a)		High Stock Effect (a)	
		Low Stock (s)	High Stock (s)	Low Stock (s)	High Stock (s)
Additive-Separable	Low increase	-5.28	-1.12	-5.36	-1.61
	High increase	-7.07	-6.84	-18.04	-1.16
Cobb-Douglas	Low increase	-3.97	10.19	-5.12	-2.03
	High increase	-7.44	-11.37	-16.16	-1.05

the resource depletion, until a certain stock level is reached. Thereafter, the stock effect dominates and we fall back on the dynamics discussed above (the two types of consumption decrease).

Conclusion: Policy Recommendations

The main feature of our model is to combine nondepletive traditional goods, the love of nature and market goods in the objective function of the resource owners/users. This feature ensures a new type of results and dynamics in the relation between poor access to (productive) capital and the depletion of the natural resource base: depending on the state of the resource stock, the impact of the average resource price paid to the producers (here through the monopolist's cheating measured by α) on their consumption of market goods can be either positive or negative. At high stock levels, i.e., above a critical level \bar{S} , lower prices lead to increased market consumption, which can only be achieved by accelerating resource extraction. At low stock levels, lower prices lead to decreased market consumption and therefore more resource conservation.

In contrast with others (e.g., Barbier 2010), these results show that a poverty - environmental degradation trap is not inevitable in our setting, despite the producers' poor access to assets, markets and income opportunities. The mechanism of effort allocation between depletive and nondepletive activities is triggered by the relative marginal utility of traditional and market consumption, the latter being indirectly linked to resource extraction. Further, as long as the critical stock level \bar{S} defined in this paper is above the minimum viable stock, complete resource depletion will not happen. The nonlinear relationship between poverty and degradation reflects the notion of an environmental Kuznets curve (see Pfaff et al. 2004). Such results illustrate the importance of including interactions between the use of natural resources, human well-being and development in the context of sustainable development policies.

The theoretical results above are largely confirmed by our simulations, which are calibrated on field data and observations. The simulation results highlight the impact of the stock effect of old-growth forest on the different decision variables of the gaharu producers. Through the interplay of decision variables described above, the effect of the stock of forest on the production of gaharu determines the income and the substitution effects of a decrease in gaharu prices (an increase of the share of high-quality gaharu paid at the low-quality price). Our results imply that the policies aimed at the economic development of the forest communities and at forest conservation should consider the different scenarios described here. For instance, PNG authorities started to educate forest authority (PNGFA) and customs officers about gaharu grading and pricing in the early 2000s. Such measures might reduce what we call “cheating” in our model, especially if information spills over to producers, and increase the price they receive (though it would not remove the monopsonistic nature of the market in PNG). Crucially, our results show that depending on the stock level of old-growth forest, such interventions can have positive or negative effects on the income of producers and on the extraction of the resource. We expect that our model is applicable and testable where the extraction of other nonrenewable resources can be substituted by nondepletive activities, in communities who attach a high “existence” or “amenity” value to the environment they live in. An example coming to mind is the mining of minerals in isolated indigenous communities in tropical forests. Future research work may include attempts to investigate explicitly the link between such policies and producers’ well-being and to endogenize the monopsonist’s behavior, or to generalize the model by relaxing the assumption of economic isolation and zero capital accumulation.
