A new approach for efficient second-harmonic generation using diode lasers is presented. The experimental setup is based on a tapered amplifier operated in a ring resonator that is coupled to a miniaturized enhancement ring resonator containing a periodically poled lithium niobate crystal. Frequency locking of the diode laser emission to the resonance frequency of the enhancement cavity is realized purely optically, resulting in stable, single-frequency operation. Blue light at 488 nm with an output power of 310 mW is generated with an optical-to-optical conversion efficiency of 18%. © 2010 Optical Society of America

Visible-light generation by second-harmonic generation (SHG) of diode laser radiation using enhancement cavities with a nonlinear crystal is a well-established technique. The major problem is to lock the laser emission to the resonance frequency of the enhancement cavity or vice versa. The two common approaches are electronic or optical locking. In electronic locking, an error signal proportional to the frequency detuning is generated [1–3]. This signal can be applied, e.g., to the driving current of the diode laser [1] or to a piezo-controlled mirror to adjust the optical length of the enhancement or reference cavity to tune both resonators to a common resonance. In optical locking, light is injected into the laser to force the laser emission to the resonance frequency of the enhancement cavity without further active stabilization [4]. Therefore, the enhancement cavity itself is used to filter out the appropriate frequency [5]. To improve the stability of the laser output, optical locking can be combined with electronic locking [6–8].

Wigley et al. [9] proposed an optical locking setup where a ring resonator with a laser diode as gain element is coupled to a standing-wave resonator. Frequency selection is realized by the standing-wave resonator and a dielectric spike filter. An alternative method for generation of 488 nm radiation in a passively stable system is based on sum-frequency generation of a tapered diode laser and a solid-state laser [10].

In our approach we propose a new laser system based on two passively coupled ring resonators. The master ring resonator has a tapered amplifier (TA) as the gain element, while the enhancement ring resonator contains a periodically poled lithium niobate (PPLN) crystal for efficient SHG. The enhancement ring resonator is set up as a miniaturized device and is singly resonant for the IR light. Single-frequency operation of the coupled laser system is provided by two frequency-selective elements, the SHG ring resonator and an additional grating.

The experimental setup is shown in Fig. 1. The output beam of the TA (λ = 976 nm) is collimated with an aspherical lens (L1: f = 8 mm, NA = 0.5) and an additional cylindrical lens (L2: f = 150 mm) for the slow axis direction. In this way the beam is symmetrized and nearly free of astigmatism. An optical diode (OD) with 40 dB of isolation protects the amplifier from damage due to backreflected light and forces unidirectional operation of the amplifier. With a spherical lens (L3: f = 50 mm) the beam is focused into the SHG ring resonator, which consists of four mirrors (M1–M4), the PPLN crystal and two gradient index (GRIN) lenses.

The beam waists of the focus are determined to \( w_{\text{slow}} = 21 \mu m \) and \( w_{\text{fast}} = 22 \mu m \) for the slow and fast axis, respectively, with a remaining astigmatism of 0.2 mm. A part of the IR light is transmitted via the beam splitter (BS) and directed to the optical diode (OD). The second harmonic is then generated in the PPLN crystal and passes through the additional grating (G) before being measured by the diagnostics (D) and compared to the detected IR light. The optical diode (OD) protects the amplifier from backreflected light and forces unidirectional operation of the amplifier.

Fig. 1. (Color online) Experimental setup of the coupled resonators with a TA and a miniaturized ring: L1, aspherical lens; L2, cylindrical lens; OD, optical diode; BS, beam splitter; D, diagnostics; L3, spherical lens; mirrors M1–M4; PPLN, periodically poled lithium niobate crystal; GRIN, gradient index lenses; L4, spherical lens; HWP, half-waveplate; PBS, polarizing beam splitter; G, holographic diffraction grating; L5, aspherical lens.
beam propagation factors are measured to be $f=125 \text{ mm}$. This light is fed back to the rear facet of the TA via a holographic diffraction grating ($G: g =1800 \text{ mm}^{-1}$) and an aspherical lens ($L_5: f=11 \text{ mm}, \ NA=0.3$). To operate the TA in an appropriate regime, a variable attenuator is used to adjust the amount of feedback light. The attenuator is formed by a rotary $\lambda/2$ waveplate and a polarization beam splitter.

The TA is designed with separate contacts for the 1 mm long ridge and the 3 mm long tapered section, and therefore the amplifier is mounted $p$-side up. Both facets are antireflection (AR) coated with a reflectivity of $R<10^{-4}$. The waveguide core in the direction of the fast axis is built as a so-called asymmetric super-large optical-cavity (aSLOC) [11]. This reduces the vertical far field angle as well as the optical power density allowing operation at higher maximum optical output power.

To characterize the TA, a Littrow-type external resonator is used with the same holographic diffraction grating. At injection currents of 150 mA for the ridge and 3000 mA for the tapered section, an optical output power of 1770 mW is measured. The laser emission is tunable from 950 nm to 990 nm at a gain maximum of 974 nm at $T=20.00^\circ \text{C}$ and a corresponding linewidth <50 pm. The corresponding beam propagation factors are measured to be $M^2_{\text{fast}}=1.4$ and $M^2_{\text{slow}}=1.7$ using a scanning slit technique and the second-order moments to determine the beam-waist radii (modified BeamScope P5, DataRay, Inc.).

The PPLN bulk crystal ($l=10 \text{ mm}$) is manufactured by HC Photonics. It is made of congruent melt with 5% MgO doping. The poling period is 5.36 $\mu\text{m}$ for optimal SHG of 976 nm at a temperature of 50$^\circ \text{C}$. A conversion efficiency of 2.7%/$\text{W}$ is measured in a single-pass setup. Both facets of the crystal are AR coated for the fundamental and second-harmonic wave with a residual reflectivity of each facet of $R_{976 \text{ nm}}<0.5\%$ and $R_{488 \text{ nm}}<1.0\%$, respectively.

All parts of the SHG ring resonator are mounted on a glass substrate with a size of 19.5 mm x 8.5 mm, where the PPLN crystal is the size-limiting element. Resonator stability is realized by two GRIN lenses ($f_1=f_2=6.6 \text{ mm}$) that are placed symmetrically to the crystal. The lenses are AR coated for the fundamental wave with a residual reflectivity of each surface of $R<0.2\%$. By variation of the distance between the two lenses, the beam waist can be adjusted and mode matching can be optimized. The mirror reflectivities are calculated based on input power, efficiency of the crystal, and resonator losses due to nonperfect AR coatings and absorption [12]. Impedance matching is one of the most important aims that can be realized with a reflectivity of the incoupling mirror M1 of $R=0.96$. It turned out that the impedance-matching condition is almost fulfilled for a wide range of cavity losses and reflectivities of the outcoupling mirror M2, and thus the reflectivity of mirror M2 can be chosen without affecting this aim. For sufficient IR light transmission the reflectivity of mirror M2 is chosen to $R=0.96$. Mirrors M3 and M4 are highly reflecting for the fundamental. The blue light is coupled out via mirror M3. The finesse of the SHG ring resonator is estimated from the reflectivities of the mirrors and resonator losses to be approximately 20 including the losses due to SHG. The optical path length of the SHG ring resonator equals 50 mm, which corresponds to a free spectral range (FSR) of 6 GHz.

To achieve stable operation, the miniaturized ring resonator is isolated in a Teflon housing and temperature stabilized to 27.10±0.01$^\circ \text{C}$. The temperature of the tapered amplifier is set to 20.00±0.01$^\circ \text{C}$. At injection currents of 150 mA for the ridge and 2500 mA for the tapered section, the output power of the TA is measured to be 1680 mW. The power incident at the SHG ring is 1470 mW from which 410 mW is reflected. We assume that this is due to spatial mode mismatch because of the spatial emission properties of the TA with $M^2>1.4$ and the fundamental mode operation of the SHG ring. Furthermore, the experimentally determined finesse was 10. We assume that this reduction by a factor of two is caused by a mode mismatch between the incident light and the SHG resonator mode. Over a period of 10 min a blue output power of 310 mW is observed with fluctuations below 1%. The spectrum of the IR light is measured with an optical spectrum analyzer (OSA); see Fig. 2. No side modes are observed, and the spectral emission bandwidth of 50 pm in this measurement is given by the resolution limit of the OSA. The highest conversion efficiency at the chosen temperature of the PPLN crystal is observed at an IR emission wavelength of 975.2 nm.

Single-frequency operation of the coupled resonators is proved by an additional spectral measurement with a scanning Fabry–Perot interferometer (FPI) of type FPI 100 by Toptica Photonics (FSR=4 GHz, $\mathcal{F}>400$). The two lines in Fig. 2 are separated by the FSR of the scanning FPI, and the linewidth of the IR light is determined to be 50 MHz (sweep time 15 ms); see the inset of Fig. 3.

The diffraction grating provides a spectral resolution of 15 GHz, which is realized by nearly full illumination of the 15-mm-long grating. By tilting the grating it is possible to tune the IR laser emission in steps of the FSR of the SHG ring resonator. Thus,

![Figure 2](https://example.com/fig2.png)

Fig. 2. Spectrum of the IR light measured with an OSA (resolution limit 50 pm).
when the temperature of the crystal is changed simultaneously, the blue laser emission can be tuned in steps of 12 GHz. The tuning range of the blue light is limited by the used crystal oven having an upper temperature limit of 30°C. However, wavelength tuning of 1.5 nm was demonstrated in a single-pass setup using the same PPLN crystal [13].

The blue output beam is nearly diffraction limited with beam propagation factors of \( M_{\text{fast}}^2 = 1.05 \) and \( M_{\text{slow}}^2 = 1.07 \) for the fast and slow axis, respectively. The SHG ring resonator acts as an efficient mode filter with fundamental mode oscillation only.

In summary, a diode-laser-based system of two coupled ring resonators for efficient SHG is presented. A tapered amplifier in a low-finesse ring resonator is used to drive SHG in a second ring resonator with nonlinear crystal. Because of the high output power of the TA and the high efficiency of the PPLN crystal, the SHG ring resonator is designed with a relatively low finesse. The adjustment of the laser system is uncritical compared to common high-finesse setups. Frequency locking of both resonators is realized purely optically. Stable output power of 310 mW of blue light at 488 nm is observed. The emitted blue light is single frequency with a linewidth of 50 MHz and nearly diffraction limited with \( M^2 < 1.1 \) for both axes. This scheme can be adapted to other diode lasers to generate its second harmonic in an efficient way.
