Background. The pathogenetic mechanisms of fetal growth restriction associated with placental malaria are largely unknown. We sought to determine whether placental malaria and related inflammation were associated with disturbances in the insulin-like growth factor (IGF) axis, a major regulator of fetal growth.

Method. We measured IGF-1 and IGF-2 concentrations in plasma from 88 mother-neonate pairs at delivery and IGF binding proteins 1 and 3 (IGFBP-1 and IGFBP-3, respectively) in cord plasma from a cohort of Papua New Guinean women with and without placental malaria. Messenger RNA levels of IGF-1, IGF-2, and the IGF receptors were measured in matched placental biopsy specimens.

Results. Compared with those for uninfected pregnancies, IGF-1 levels were reduced by 28% in plasma samples from women with placental Plasmodium falciparum infection and associated inflammation (P = .007) and by 25% in their neonates (P = .002). Levels of fetal IGFBP-1 were elevated in placental malaria with and without inflammation (P = .08 and P = .006, respectively) compared with uninfected controls. IGF-2 and IGFBP-3 plasma concentrations and placental IGF ligand and receptor messenger RNA transcript levels were similar across groups.

Conclusion. Placental malaria-associated inflammation disturbs maternal and fetal levels of IGFs, which regulate fetal growth. This may be one mechanism by which placental malaria leads to fetal growth restriction.

Placental malaria is a leading cause of low birth weight (LBW) in Africa, resulting in 75,000–200,000 infant deaths each year. In these settings, LBW is more commonly due to fetal growth restriction (FGR) rather than preterm delivery [1,2]. The sequestration of Plasmodium falciparum–infected erythrocytes (IEs) in the placental intervillous spaces, termed placental malaria, can trigger the recruitment of inflammatory cells and production of cytokines, which are strongly associated with LBW [3–5]. The biological mechanisms leading to LBW are not known, but placental insufficiency and endocrine disturbances may underlie the pathogenesis.

The placenta functions as an endocrine organ and transmits hormonal signals between the mother and the developing fetus to ensure adequate support for sustained fetal growth. Few studies have examined maternal endocrine profiles in the context of malaria in pregnancy [6–8], and no study has investigated the relationship between growth-regulating hormones and LBW in placental malaria.

The insulin-like growth factor (IGF) system is the most influential growth-promoting factor in fetal life [9], with roles in regulating placental development and function, transplacental exchange of nutrients, and fetal growth. In mice, genetic ablation of insulin-like growth
factor 1 gene (Igf1) or insulin-like growth factor 2 gene (Igf2) decreases birth weight by 40% [10], and double knock-out of Igf1 and Igf2, or of the IGF-1 receptor gene (Igf1r), further restricts fetal growth [10]. The liver is the main source of circulating IGF-1 in postnatal life [11], but during pregnancy the placenta and the fetus secrete IGFs and regulatory proteins. Fetal IGF-1 and IGF-2 promote fetal growth but have differential actions, which have been attributed to distinct interactions with receptors.

The IGF receptors (IGF-1R and IGF-2R) mediate IGF activity and are abundant in all placental cell types [12] and in the microvillus plasma membrane of the syncytiotrophoblast [13]. Activation of IGF-1R stimulates cell signaling cascades [14] that lead to proliferation, survival, and fetal growth promotion [9], whereas IGF-2R lacks the cell signaling domain [11], acting as a sink to sequester free IGF-2, and is considered antimitogenic.

Bioactivity of the IGFs is modulated by the IGF binding proteins (IGFBPs), which transport circulating IGFs. IGFBPs have greater ligand affinity than IGF receptors [15] and thus sequester circulating IGFs to restrict their interactions with the receptors. IGFBP-1 and IGFBP-3 are expressed in abundance at the maternal-fetal interface [15]. IGFBP-1 is an important negative short-term regulator of IGF bioactivity, and levels fluctuate in response to maternal stress and nutritional intake [16–18]. Alterations in the absolute level and bioavailability of the IGFs in maternal, fetal, and placental compartments are implicated in other causes of FGR [9, 11, 19, 20]. However, the relationship between placental malaria, the IGF axis, and birth weight has not been explored.

We investigated whether placental malaria and the associated inflammation impacted on the IGF system at delivery and whether changes in the IGF axis were consistent with the IGF profile observed in FGR of other etiologies.

**METHODS**

**Study Design**

Pregnant women attending antenatal care at Alexishafen Health Centre, Madang, Papua New Guinea, between September 2005 and October 2007 were recruited to a longitudinal study of malaria in pregnancy, following written informed consent. At delivery, babies were weighed, Ballard scores were used to estimate gestational age, and maternal hemoglobin levels were measured. Maternal and cord blood was collected in K2-ethylmagnesium heparinate vials (BD), and separated plasma was frozen at –80°C. A random sampling of placental biopsy specimens were either collected into 10% neutral buffered formalin for histological examination for placental malaria infection or frozen at –80°C in RNAlater (Ambion) for RNA analysis. The Medical Research Advisory Council of Papua New Guinea and the Human Research Ethics Committee of Melbourne Health, Australia, approved the study. Samples used in the present study are from a subset of participants recruited.

**Placental Histology and Inclusion Criteria**

Placental histology was examined as described by Rogerson et al [3]. Full-thickness Giemsa-stained biopsy specimens were examined, and IEs, monocytes containing malaria pigment, and malaria pigment in fibrin were noted. Where IEs were detected, 500 intervillous cells (IEs, erythrocytes, or otherwise) were counted, and placentas were classified as either placental malaria without inflammation (≥1% IEs and <1% pigmented monocytes), denoted as placental malaria (PM), or placental malaria with monocyte infiltrate (PMI) (≥1% IEs and ≥1% pigmented monocytes). Plasma samples from a subset of ~30 women from each group, including uninfected controls (no evidence of either IEs or pigmented monocytes) with live singleton deliveries were randomly selected for IGF assays.

**Placental RNA Extraction and Real-Time Quantitative Polymerase Chain Reaction (qPCR)**

RNA extraction from placental tissue biopsy specimens was performed using Trizol reagent (Invitrogen), according to the supplier’s instructions. Contaminating DNA was removed by DNase treatment (Ambion) and confirmed by a lack of amplification signal following real-time qPCR. Two micrograms of RNA were reverse transcribed according to supplier’s recommendations (Superscript III; Invitrogen), and complementary DNA was diluted 2-fold in DNase-free water and stored at –20°C until use. Real-time qPCR was performed in duplicate using a SYBR Green master mix (Applied Biosystems) dispensed by liquid handling robot (Eppendorf) on an ABI 7900HT real-time PCR machine (Applied Biosystems). Primer sequences were derived from those in previous studies or designed using Primer Express (Supplementary Table 1). Transcript levels of target genes (IGF1, IGF2, IGF1R, and IGF2R) were quantified in 88 placental biopsy specimens by real-time qPCR using a ratio of transcription (R) determined by the equation $R = \frac{[E(target)]^{ΔCt}}{[E(\text{housekeeper})]^{ΔCt}}$, which corrects for any potential differences in PCR efficiency (E) between primer pairs, where the difference in cycle threshold (ΔCt) between control and sample, and where $E = 10^{-\text{slope}}$. Slope is calculated from the fluorescence generated by a 7-point standard curve of pooled complementary DNA for each primer pair. The relative amplification efficiency of each target gene was >93% of the housekeeping gene tyrosine 3-monooxygenase/tryptophan 5-monooxygenase activation protein, zeta polypeptide (YWHAZ).

**Enzyme-Linked Immunosorbent Assay (ELISA)**

Total IGF-1 and IGF-2 concentrations in cord and maternal plasma were determined by ELISA in 88 mother-infant pairs. Four additional maternal samples that met selection criteria but lacked the corresponding cord sample were included. Cord IGFBP-1 and IGFBP-3 levels were measured by ELISA in 87 (due
to volume limitation) and 88 samples, respectively; IGFBP-1 concentrations in cord plasma were log-transformed to normalize the data before analysis. Intra- and inter-assay variability did not exceed 6%, except for IGF-2 and IGFBP-3 ELISAs, which varied between assays by 8.5% and 6.5%, respectively. ELISA kits were purchased from Diagnostic Systems Laboratory.

**Statistical Analysis**

Univariate analysis was performed using GraphPad Prism software version 4.03 (Graphware). Parametric data, represented as mean and standard deviation (SD), were compared using the Student t test or analysis of variance (ANOVA) for ≥3 groups. Nonparametric data, shown as median and interquartile range (IQR), were compared using the Kruskall-Wallis test. Correlation analyses used the Pearson correlation r for parametric analysis or the Spearman ρ for nonparametric correlation. Linear regression was used to determine the slope of the correlation and is expressed as the correlation coefficient β (± standard error). Multivariate analysis and odds ratio (OR) calculations were performed using Stata software (version 10; Stata). Results for which P ≤ .05 were considered to be statistically significant.

**RESULTS**

**Participant Characteristics at Delivery**

Table 1 summarizes the clinical characteristics and placental histology of the 92 participating women. Three-quarters of all PMM cases had IEs of ≥1% and ≥1% pigmented monocytes, whereas 60% of PM cases had <1% of IEs. In total, 58 women had placental malaria; 27 were positive for both placental malaria and monocyte infiltrate (PMM), and 31 had placenta malaria infection only (PM). Thirty-four women were uninfected. Maternal age (P = .03), gravidity (P = .02), and gestational age at delivery (P = .05) of the women with PMM were significantly lower than those of the uninfected controls, whereas hemoglobin levels were unchanged between groups.

**Placental Malaria With Inflammation Is Associated With Decreased Birth Weight**

The mean birth weight of infants from pregnancies with PMM was 370 g less than that for infants delivered in the absence of infection (P = .01) (Table 2). Infants delivered from pregnancies with PM were 100 g lighter than infants born from uninfected women. Women with PMM had 3 times the risk of delivering a LBW infant (weight, <2500 g; OR, 3.0; 95% confidence interval [CI], 0.9–10.4; P = .08) compared with uninfected women, whereas there was no increased risk in women with PM alone (OR, 0.8; 95% CI, 0.2–3.4; P = .8). Because women with PMM and uninfected women had significantly different maternal age, gravidity, and gestational age at delivery, multivariate analysis was performed to determine the relative impact of placental malaria with or without monocyte infiltrate on birth weight (Table 2). After adjusting for gestational age, PMM reduced mean birth weight by 200 g compared with babies of uninfected women (P = .04). Furthermore, when we stratified women by gravidity and controlled for the influence of gestational age and maternal age, the reduction in birth weight with PMM was limited to primigravidae, who delivered infants nearly 300 g lighter than those of matched uninfected women (P = .02) (Table 2).

**Placental Malaria and Inflammation Reduce Maternal IGF-1 Concentrations**

We measured levels of IGF-1 and IGF-2 protein by ELISA in maternal plasma samples collected at delivery. The mean total IGF-1 concentration in women with PMM was 28% lower than in uninfected women (P = .007) (Figure 1A), whereas IGF-2 levels were similar across all cohorts (Figure 1B). In the whole cohort, maternal IGF-1 concentration was not correlated with birth weight (P = .4), gestational age (P = .4), or gravidity (P = .2).

**NOTE.** Data are mean (SD). Women with placental malaria (PM) infection and monocyte infiltrate (PMM) were on average younger and primigravidae and delivered younger and lighter neonates than uninfected women. The percentage of infected erythrocytes (IEs) and monocytes were determined from 500 cells counted from the intervillosus spaces in infected placenta only. ANOVA, analysis of variance.

but among women with PMM there was a significant negative correlation between the extent of monocyte infiltrate and maternal IGF-1 levels (n = 27; r = −.4; P = .05) (Figure 1C).

**Placental Malaria Does Not Alter Placental IGF Transcript Levels**

We measured expression of messenger RNA (mRNA) transcripts for IGFBP-3 in 88 placental biopsy specimens by real-time qPCR (Table 3). Ct values for YWHAZ were not different between groups (Kruskall-Wallis test; P = .7). Transcript levels of all 4 genes did not differ significantly between placenta with and without malaria infection and/or monocyte infiltrate.

**Total Levels and Bioavailability of Fetal IGF-1 Are Reduced in Placental Malaria and Monocyte Infiltrates**

To evaluate the effect of placental malaria and the associated inflammation on the fetal compartment of the IGF axis, we measured concentrations of total IGF-1, IGF-2, IGFBP-1, and IGFBP-3 in cord plasma samples.

IGF-1 concentration was reduced by 25% in the PMM group compared with infants from uninfected placentas (P = .002) (Figure 2B), whereas IGF-2 concentrations in cord plasma were similar across the 3 groups (ANOVA value, .9) (Figure 2A). Infants delivered from pregnancies with PM alone had IGF-1 concentrations that were intermediate between those of the uninfected and PMM groups. Cord IGF-1 concentration did not vary with gravidity (n = 88), nor did it vary with placental parasitemia in babies of infected women (n = 57) nor with monocyte infiltrate in babies with PMM (n = 26). Cord IGF-1 concentration was weakly correlated with birth weight (r = .3; P = .06) (Figure 3A) and to a lesser extent gestational age (n = 80; r = .2; P = .07). After adjusting for gestational age, the relationship between cord IGF-1 concentrations and birth weight was substantially strengthened (R^2 = .5; P = .001).

Compared with infants born from uninfected pregnancies, the median IGFBP-1 concentration was 80% higher in infants born in the presence of PM (P = .006) and 40% higher in infants delivered to the PMM group (P = .08) (Figure 2C). No significant differences were observed in cord plasma IGFBP-3 concentration between uninfected and PM categories (ANOVA F[2, 81]; .2; P = .9) (Figure 2D). However, because of the biological relationship between ligand and binding protein, the ratio of log IGF-1 concentration to log IGFBP-3 concentration (as proxy for free IGF-1 [21]) was examined in relation to placental infection (Figure 2E). Compared with uninfected pregnancies, the mean estimated free fetal IGF-1 level was reduced by 5% in PM cases (P = .02) and by 10% in the presence PMM (P < .001).

To further examine the possibility that diminished fetal IGF-1 is a key pathogenic mechanism leading to LBW in placental malaria with inflammation, cord IGF-1 levels were compared between normal-birth-weight (≥2.5 kg) and LBW (<2.5 kg) infants delivered from uninfected pregnancies and those with PM and PMM (Figure 3B). Both normal-birth-weight and LBW infants from the PMM group had lower IGF-1 concentrations (P = .02 and P = .04, respectively) than the respective birth weight group from uninfected pregnancies (Figure 3B), and LBW infants from the PMM group displayed the most severe reduction in IGF-1 concentration.

**DISCUSSION**

Although the causal relationship between placental malaria and LBW is well recognized, little is known about the pathogenetic mechanisms leading to FGR in malaria. We investigated whether placental malaria and the associated inflammation caused disturbances in the IGF axis in the mother, placenta, or fetus. In agreement with previous studies in areas where malaria is endemic [3, 4], the greatest impact of placental malaria on birth weight was observed in infants born with placental malaria and monocyte infiltrate, which was most common in primigravidae.

We have identified changes in the IGF axis in mothers and infants with placental malaria and inflammation consistent with
IGF-1 level and birth weight [22, 23], and it is unlikely that maternal IGF-1 levels during pregnancy could be used to predict pregnancies at risk of LBW.

Although maternal IGFs are not transferred across the placenta, they promote fetal growth indirectly through modulation of placental nutrient partitioning. Nutrient transporters are important downstream targets of the IGF system, and physiological levels of IGF-1 stimulate in vitro glucose and amino acid transporter expression and activity in trophoblast cell cultures [24, 25]. The malaria-associated inflammatory events reducing maternal IGF-1 may lead to impaired nutrient delivery to the fetus.

Several physiological explanations could account for the diminished maternal IGF-1 concentrations we have observed in placental malaria with inflammation. Previous studies have shown the IGF axis is influenced by hypoxia, nutrition, cortisol [26], and inflammatory cytokines [27–29]. Although there is no evidence that placental malaria causes hypoxia, [30], elevated levels of pro-inflammatory cytokines [5, 31–33] and glucocorticoids [6, 8] observed during malaria in pregnancy could influence the IGF axis. Whether these processes are responsible for the decreased IGF-1 levels (and therefore fetal growth) that we have observed in placental malaria with inflammation deserves further investigation. Whatever the intermediate signal, the lack of a pronounced effect of parasite sequestration alone on circulating IGF-1, coupled with the strong negative association between inflammatory load and maternal IGF-1 levels, suggests that the chronic nature of PPM infections coupled with the inflammatory processes are the driving force reducing IGF-1 in the maternal compartment at delivery.

Throughout pregnancy, the fetal liver synthesizes IGFs [15], which act in part to regulate materno-fetal glucose transfer according to fetal demand. IGFs also have a direct trophic effect in fetal target tissues, via activation of the IGF-1R expressed in fetal organs. Decreased levels of fetal IGF-1, such as we have described in placental malaria and inflammation, are likely to negatively affect fetal growth through decreased cellular proliferation and indirectly by limiting transplacental passage of nutrients. Indeed, evidence from our study supports a pathogenetic link between attenuated IGF-1 level and birth weight, as cord IGF-1 level was

positively associated with birth weight, and LBW infants from PMM displayed the most severe reduction in IGF-1 levels. These observations are consistent with other studies, in which cord blood IGF-1 concentration at term is positively correlated with fetal growth [34–36] and is diminished in human FGR [9, 11, 20, 37]. Furthermore, the reduction in cord IGF-1 concentration and concomitant reduction in birth weight in this study are consistent with the 200–500 g decrease in birth weight reported in other studies with similar perturbations in IGF levels [34, 38].

The mechanisms by which fetal IGF-1 levels are decreased in human studies remain unclear (although it may be inversely related to cortisol levels [37]), and in animal models, restriction of maternal nutrition [39], placental blood flow [40], and oxygen [41] all decrease fetal IGF-1 concentrations.

IGF-2 is more abundant in fetal circulation than IGF-1 [34], but the relationship between cord IGF-2 levels and birth weight is inconsistent [20, 34–36, 42, 43]; cord IGF-2 level may be correlated with ponderal index and placental weight [36], but neither measure was available for the present cohorts. Our data are consistent with published studies in associating placental disease at delivery with decreased IGF-1, rather than IGF-2 [20, 35, 36]. Nevertheless, IGF-2 is an important regulator of placental development and fetal growth during early pregnancy. Further studies should examine whether perturbed levels of
The decreased ratio of IGF-1 to IGFBP-3 we report in placental malaria is a surrogate measure of free IGF-1 [21] and supports the notion that free, as well as total, IGF-1 at delivery is reduced in infants born to mothers with PM, and to a greater extent, in placental malaria with monocyte infiltrate.

By mRNA analysis of placental tissue, we did not find any significant changes in IGF-related gene transcription. In contrast, significantly increased placental IGF1 and/or IGF2 mRNA levels have been reported in several but not all human studies of FGR [45–49]. Some of these studies have examined placental mRNA transcript levels in smaller sized studies than ours [46, 48], which suggests that our study size was adequately powered. The observation that placental transcripts for components of the local IGF system remained unchanged with malaria infection and associated inflammation implies that autocrine effects of IGFs are perhaps not the locus for modulation of fetal growth in malaria-affected pregnancies. Alternatively, closer examination of IGF levels in the syncytiotrophoblast layer by laser capture microdissection might reveal differences that are not apparent in biopsied placental tissue [30].

A potential limitation to this study is that the detection method used for IGF-1 and IGF-2 measured total (bound and unbound fractions) rather than bioactive (free) ligand, which constitutes ~1% of total IGF [20]. However, concentrations of total IGF correlate with those of free IGF [20, 34] and frequently associate with clinical indices of fetal growth [20, 35, 36, 38, 46]. We determined the ratio of IGF-1 to IGFBP-3 in cord samples as a proxy measure of free IGF-1 [21]. A further consideration is that the phosphorylation state of IGFBP-1 during gestation affects the ligand binding activity [11]. Because measurement of phosphovariants is both time- and cost-intensive, we quantified total IGFBP-1 by ELISA, which does not discriminate between phospho-isoforms but has been validated in other studies [20, 36, 38]. To minimize possible proteolytic degradation of IGFBP-3, which may overestimate IGFBP-3 levels, we restricted samples to a single cycle of freezing and thawing. Future studies that employ more sophisticated detection of IGFBP-1 phospho-isoforms and that take into account free and total fractions of IGF-1 and IGF-2 may reveal additional functional subtleties.

Current theories on the pathogenesis of LBW associated with placental malaria-induced inflammation center on the conflicting immune environment between resolution of infection and the requirement for continued fetal growth. The release of pro-inflammatory cytokines [5, 31, 32] and monocyte infiltrates in the placental intervillous spaces [4] are associated with LBW, but the physiological impact of the inflammatory environment on placental function and fetal growth has not been studied extensively. To date, disturbances in the IGF system relating to fetal growth have been described in preeclampsia, asthma, nutritional deprivation, and maternal stress and in diabetic pregnancies [38, 45], and our study adds malaria to this list. Interventions that specifically target growth restriction through IGF therapy have been shown to prevent FGR in sheep [50] but have yet to be applied to disease in humans. Whether perturbations of the IGF system in humans are an underlying cause of or response to growth restriction remains to be fully elucidated.

This study provides strong evidence of concordant disturbances in the maternal and fetal compartments of the IGF axis with placental malaria and associated inflammation, which
have the potential to compromise nutrient partitioning to the fetus and may play a central role in the development of LBW due to FGR in malaria-infected pregnancies.
