ABSTRACT

Hepatocellular carcinoma (HCC) is a common cause of cancer-related deaths worldwide. Despite advances in systemic therapies, patient survival remains low due to late diagnosis and frequent underlying liver diseases. HCC diagnosis generally relies on imaging and liver tissue biopsy. Liver biopsy presents limitations because it is invasive, potentially risky for patients and it frequently misrepresents tumour heterogeneity. Recently, liquid biopsy has emerged as a way to monitor cancer progression in a non-invasive manner. Tumours shed content into the bloodstream, such as circulating tumour cells (CTCs), circulating nucleic acids, extracellular vesicles and proteins, that can be isolated from biological fluids of patients with HCC. These biomarkers provide knowledge regarding the genetic landscape of tumours and might be used for diagnostic or prognostic purposes. In this review, we summarize recent literature on circulating biomarkers for HCC, namely CTCs, circulating tumour DNA (ctDNA), RNA, extracellular vesicles and proteins, and their clinical relevance in HCC.

Keywords: liquid biopsy; circulating tumor cells (CTCs); circulating tumor DNA (ctDNA); hepatocellular carcinoma; biomarker, liver cancer.
1. INTRODUCTION / BACKGROUND

Hepatocellular carcinoma (HCC) corresponds to >80% of primary liver cancers worldwide [1]. HCC is the 3rd leading cause of cancer-related death in the world [2], and in contrast to other types of cancer, the disease burden of liver cancer has been increasing over the last decades [3]. HCC occurrence is highly variable across different geographic regions, ethnic groups and between men and women. The majority of HCC cases develop on the background of chronic liver diseases, and are usually associated with advanced fibrosis or hepatic cirrhosis. Although nearly 80% of HCC cases are related to chronic viral hepatitis [4], other liver diseases such as non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH) associated with metabolic syndrome and obesity are the most relevant underlying conditions in the remaining cases. There are reports of HCC without cirrhosis in a significant proportion of those cases [5, 6]. The remarkably poor outcome of patients with HCC (5-year survival rate of 5%) is related to the difficulty in surveillance in at risk populations and the lack of widely available diagnostic tools for early detection, resulting in patients being diagnosed with advanced non-resectable tumours [7].

On the basis of proteome, gene expression and genome profiling, HCC cells have been classified into two major groups: a highly-aggressive “proliferative class”, which is mainly characterized by the inactivation of TP53, activation of the TGF-β pathway and Wnt proliferation signals, positivity of stemness markers and high alpha-fetoprotein (AFP); and a heterogeneous “nonproliferative class” related to CTNNB1 gene and TERT promoter mutations, the maintenance of a hepatocyte-like phenotype and the hypermethylation of CDKN2A and CDH1 [8-10]. Therefore, each subtype presents specific genetic and epigenetic characteristics that determine the patient’s prognosis and response to treatment, although a direct translation of these findings into clinical management has not yet been achieved [11].

Currently, surveillance of patients at risk for HCC is the most effective measure to decrease the burden of the disease. Chen et al. implemented a surveillance protocol for HBV surface antigen-positive (HBsAg) individuals (n=5,581) in China, and showed that a six-monthly ultrasound examination and serum α-fetoprotein (AFP) level measurement (20µg/L cut off) was an effective strategy in the early detection of primary liver tumours in screened patients (29.6%) when compared to the unscreened group (6.0%) [12]. However, AFP alone has high false-negative rates (40%) and lacks sensitivity (49% – 61%) for detecting the early stages of the disease [13]. Consequently, other biomarkers have been proposed recently, such as des-γ-carboxyprothrombin (DCP), glypican-3 (GP3) and Golgi protein 73 (GP73) [14, 15]. In this context, the use of other circulating biomarkers could facilitate the earlier diagnosis of HCC, better predict patient outcomes, and monitor response to treatment. This review
aims to summarize recent literature on circulating biomarkers for HCC, with a focus on ctDNA, circulating RNAs, CTCs, proteins and exosomes.

2. MANAGEMENT OF HCC

2.1 Diagnosis

The diagnosis of HCC is made by imaging and often confirmed using other radiological findings, or less frequently, by tissue biopsy [16]. Recent advances in computed tomography (CT) and magnetic resonance imaging (MRI) have decreased the need for liver biopsy. However, diagnostic accuracy for <2cm tumours by MRI is problematic in the cirrhotic liver, with a lower sensitivity (13-67%) when compared to >3cm tumours (100%) [4, 17]. Therefore, tissue biopsy remains the gold-standard for the detection of liver cancer, despite the risks associated with it including excessive bleeding, vasovagal reaction, and pneumothorax. More importantly, a potential complication after liver biopsy is needle track seeding, which occurs when cancer cells spread along the needle track and reach other sites inside the liver, the peritoneal cavity, abdominal muscles, and the skin [18]. A meta-analysis of 8 studies reported an incidence of 2.7% of needle track seeding 17 months after biopsy [19]. Another disadvantage of biopsy is the frequent sampling error due to the high heterogeneity of the tumours, which leads to a high rate of false-negative results.

Immunohistochemistry (IHC) techniques may be used to distinguish HCC from premalignant lesions and intrahepatic cholangiocarcinoma [20]. Several markers have been proposed for the diagnosis of HCC using IHC staining of tissue samples, including glypican 3 (GP3), heat shock protein 70 (HSP70) and glutamine synthetase (GS), among which any pair was able to detect HCC with a sensitivity of 40% and specificity of 100%, with a slight decrease in the false-negative results rate when compared to conventional pathology [21, 22].

The use of AFP measurement levels for the diagnosis of HCC has been approved by the Food and Drug Administration (FDA). However, the American Association for the Study of Liver Diseases (AASLD) and the European Association for the Study of the Liver (EASL) guidelines recommend that diagnosis should rely on typical radiological findings and/or biopsy, whereas circulating biomarkers should be used as a prognostic tool. As a result, candidacy for liver transplantation based on radiological findings alone has been an accepted clinical practice in the last decade [23].
2.2 Treatment

Considering that liver cancer is predominantly associated with other chronic liver diseases, accurate evaluation of liver function is crucial to determine suitable therapies for each individual. Current therapies for HCC consist of liver transplantation, surgical resection, local ablation, transarterial chemoembolization (TACE) and systemic therapies with tyrosine kinase inhibitors (sorafenib, lenvatinib and regorafenib) [4, 20]. More recently, immune checkpoint inhibitors have also been used in the treatment of HCC [24].

In general, locoregional embolization associated with chemotherapy is the treatment of choice for unresectable tumours limited to the liver. Doxorubicin- and cisplatin-based TACE increased overall-survival in comparison to other embolization techniques [25, 26]. Systemic therapy is reserved for tumours who present extrahepatic spread or have failed at prior local therapy [27]. Sorafenib, and more recently lenvatinib, are the only first-line of systemic drugs approved by the FDA, which have demonstrated similar effects in patients’ outcomes with an improvement of ~3 months in overall-survival [28, 29]. Likewise, immune checkpoint inhibitors, mainly anti-program death receptor (PD)-1 monoclonal antibodies (nivolumab and pembrolizumab), were shown to increase the overall-survival for a minority of patients (10-20%) [30, 31]. Also, the use of an anti-vascular endothelial growth factor receptor-2 (VEGFR2) monoclonal antibody (ramucirumab) leads to an improvement in 1.2–1.8 months in overall-survival and 1.2–1.6 months in progression-free survival compared to the placebo group in a phase 3 trial involving patients (n = 292) with AFP levels ≥400 ng/mL in 20 countries [32, 33].

More recently in 2020, the FDA approved the administration of atezolizumab plus bevacizumab as the first immunotherapy regimen for the treatment of unresectable HCC. Atezolizumab is a monoclonal antibody targeting the programmed death-ligand 1 (PD-L1), which is expressed in cancer and immune cells, and blocks T-lymphocyte activation [34]. Bevacizumab is an anti-vascular endothelial growth factor (VEGF) antibody first approved by the FDA as a first-line of treatment for metastatic colorectal cancer [35]. In a phase 3 trial involving 501 treatment-naïve unresectable HCC patients, 336 individuals were treated with atezolizumab plus bevacizumab, and 165 received systemic therapy with sorafenib. Compared to sorafenib, immunotherapy lead to improved overall-survival at 12 months from 54.6% to 67.2%, and median progression-free survival from 4.3 to 6.8 months, respectively [36]. Notably, the longer time to deterioration of patient-reported quality of life and the lack of unexpected side effects were considered to determine its superiority to chemotherapy. However, Lee and co-authors[37] have shown that similar outcomes are not achieved by using atezolizumab alone, suggesting that the combined effects of both antibodies is important for the efficacy of the treatment.
Despite advances in the understanding of the molecular pathogenesis of HCC, the lack of molecular signature markers to predict response and monitor HCC treatment hinders the development of novel therapy strategies [38].

2.3 Prognosis

Several classification systems for liver cancer have been published in recent years. The OKUDA score, published in 1985, was the first to combine liver function parameters (bilirubin and albumin) and the grade of tumour invasion (more or less than 50% of liver parenchyma volume)[39]. In 1998, the Cancer of the Liver Italian Program (CLIP) score included other tumour-related parameters such as serum AFP levels, portal vein thrombosis and a more accurate measurement of liver function. The CLIP was reported as the most precise staging system by a number of authors [40, 41]. Nevertheless, the European Association for the Study of the Liver (EASL) and the American Association for the Study of the Liver (AASL) have determined the Barcelona-Clinic Liver Cancer (BCLC) staging system as the reference classification to be used in clinical trials and in day-to-day practice[42]. The BCLC staging system classifies HCC patients into 5 stages (0, A, B, C and D) and suggests appropriate therapies for each stage. For instance, curative resection of the tumour is often feasible for stage 0/A patients, whereas systemic therapy with sorafenib is indicated for stage C individuals [43]. BCLC stage is defined according to the number and size of nodules, the occurrence of extrahepatic metastasis, vascular invasion, liver function (Child-Pugh score), and the overall health status of the individual measured using the Eastern Cooperative Oncology Group (ECOG) score. However, the high heterogeneous characteristics of HCC results in variable outcomes of affected patients. There are reports of a high incidence of early recurrence after curative treatments such as surgery or liver transplantation where the overall-survival rates that can vary from over 60 months to 3 months in advanced stages [38]. Currently, AFP is the only approved biomarker with prognostic values to predict patient outcomes after transplantation, response to locoregional therapies, and survival of advanced AFP-positive HCC patients [13, 42]. The management of HCC patients is summarized in Figure 1.
High-risk individuals for HCC include patients with chronic hepatitis B or C virus, alcoholic liver disease, and other diseases that may lead to hepatic cirrhosis. These individuals should undergo an ultrasound (US) examination and a liver function test (LFT) every 6 months. HCC diagnosis is achieved by imaging examination by multiphasic computer tomography (CT) and/or magnetic resonance imaging (MRI), frequently accompanied by liver tissue biopsy. Immunostaining for glypican-3 (GPC3), epithelial cell adhesion molecule (EpCAM), hsp70 chaperone (HSP70), keratin 19 (K19), glutamine synthetase (GS) and neovascularization marker CD34 is performed. Tumour BCLC staging is defined by the size and number of nodules, liver function, portal invasion and extrahepatic metastasis. In early stages, curative options are feasible, such as the surgical removal of the tumour, ablation and liver transplantation. Loco-regional therapies using doxorubicin- or cisplatin-based transarterial chemoembolization (TACE) are indicated for BCLC B stage tumours; whereas advanced stages are treated with systemic therapies with sorafenib (first line) and regorafenib (second line). There is no efficient treatment for BCLC D stage tumours [42]. O.S. – Overall survival.

Figure 1. Management of HCC patients according to the European Association for the Study of the Liver (EASL) guidelines (2019). High-risk individuals for HCC include patients with chronic hepatitis B or C virus, alcoholic liver disease, and other diseases that may lead to hepatic cirrhosis. These individuals should undergo an ultrasound (US) examination and a liver function test (LFT) every 6 months. HCC diagnosis is achieved by imaging examination by multiphasic computer tomography (CT) and/or magnetic resonance imaging (MRI), frequently accompanied by liver tissue biopsy. Immunostaining for glypican-3 (GPC3), epithelial cell adhesion molecule (EpCAM), hsp70 chaperone (HSP70), keratin 19 (K19), glutamine synthetase (GS) and neovascularization marker CD34 is performed. Tumour BCLC staging is defined by the size and number of nodules, liver function, portal invasion and extrahepatic metastasis. In early stages, curative options are feasible, such as the surgical removal of the tumour, ablation and liver transplantation. Loco-regional therapies using doxorubicin- or cisplatin-based transarterial chemoembolization (TACE) are indicated for BCLC B stage tumours; whereas advanced stages are treated with systemic therapies with sorafenib (first line) and regorafenib (second line). There is no efficient treatment for BCLC D stage tumours [42]. O.S. – Overall survival.
3. BIOMARKERS FOR HCC

Early detection is the main challenge in the management of HCC, as currently only 20-30% of patients are eligible for surgical interventions by the time of diagnosis [44]. During progression, tumours shed content into the bloodstream, and the detection of those by-products in non-solid biological fluids is defined as liquid biopsy [45]. Although liquid biopsies are often carried out using blood, other bodily fluids can also be used, such as saliva, urine and cerebrospinal fluid [46].

For HCC, the EASL highlights the unmet need of developing new tools for early detection or prediction of response to systemic therapy by liquid biopsy [42]. One of the greatest limitations for improving patient care is the lack of biopsy tissue, considering that HCC can be diagnosed based on imaging findings alone. In this context, retrieving information about the tumour using blood or saliva sampling may be a helpful tool to improve HCC management. Compared to traditional biopsies, liquid biopsy presents a number of advantages. First, it is a minimally invasive, relatively faster and cheaper procedure, with fewer risks of complications to patients. Secondly, it is more likely to represent the tumour heterogeneity, considering recent single-cell technologies that provide insight into tumour molecular characteristics from circulating tumour cells, whereas the sampled tissue may not represent the whole tumour in a classical biopsy. Finally, liquid biopsy allows dynamic monitoring of the disease progression over time by repeated sampling [47]. The main circulating biomarkers for HCC are represented in Figure 2.
Figure 2. Schematic representation of the circulating biomarkers for HCC. During cancer progression, tumour cells shed content into the bloodstream, which is easily accessible in the peripheral blood of patients. Circulating biomarkers include circulating tumour cells (CTCs) or tumour-derived molecules such as circulating tumour DNA (ctDNA), circulating RNAs, proteins and exosomes. mRNA – messenger RNA, miRNA – microRNA, lncRNA – long non-coding RNA.
3.1 Circulating Tumour Nucleic Acid

The presence of extracellular nucleic acids, particularly DNA and RNA, was first reported in the blood of patients with systemic lupus erythematosus in 1948 [48]. Although circulating RNAs, which include mRNA, long non-coding RNA (lncRNA) and microRNA (miRNA), have shown promising results as targets for liquid biopsy, most studies regarding circulating nucleic acids are focused on cell-free DNA (cfDNA). cfDNA comprises DNA fragments (180-200bp) that are released into the bloodstream by cells undergoing apoptosis or necrosis and rapidly cleared by phagocytes and neighbouring cells [49]. While the cfDNA content in the blood of healthy individuals is usually under 100 ng per ml of blood, cancer patients often present concentrations ≥1000 ng per ml cfDNA [50]. A proportion of the cfDNA directly derived from tumour cells is further classified as circulating tumour DNA (ctDNA). In principle, ctDNA carries tumour-specific mutations and offers the possibility to obtain genetic information on the tumour in a non-invasive manner. ctDNA levels primarily depend on tumour burden, proliferation status and tumour type [44].

3.1.1 ctDNA in hepatocellular carcinoma

The use of ctDNA in HCC diagnosis is particularly interesting considering liver cancers, unlike other types of cancer, can be diagnosed without a biopsy, therefore genetic characterization of tumours is scarce [44]. Changes of plasma ctDNA can be evaluated quantitatively by measuring the total ctDNA levels in peripheral blood as well as by using a qualitative approach to identify HCC-related DNA aberrations [51].

Huang et al. [52] conducted a study in which cfDNA in plasma samples collected from 72 patients with HCC was compared to samples from 37 hepatic cirrhosis patients and 41 healthy volunteers using quantitative PCR. HCC patients had higher cfDNA levels (173 ng/mL) when compared to cirrhotic (46 ng/mL) and healthy individuals (9 ng/mL), with a positive correlation between circulating tumour DNA concentrations and tumour size, vascular invasion and metastasis. Increased cfDNA levels has also been linked to poor overall-survival rates [53], resistance to systemic therapy with sorafenib [54], and decreased response to radiation therapy [55].

Recent studies report that the number of somatic mutations detected in plasma ctDNA of HCC patients reflect the burden of the primary tumour. In a treatment-naive cohort of HCC patients with metastatic disease and tumours >5cm, at least one gene alteration was detected in 86% (n=26/30) of paired plasma cfDNA and tissue biopsy samples [56]. Using a 68-gene NGS panel, Ikeda et al. [57] reported somatic alterations in plasma ctDNA samples from 12 out of the 14 patients evaluated in the
study. The most common single-nucleotide mutations were observed in **TP53** (57%) and **CTNNB1** (29%) genes, whereas amplifications were reported in **CDK6** (14%), **EGFR** (14%) and **MYC** (14%) [57]. Similarly, in a 354-gene panel analysis performed by An et al.[58], TP53 was also reported with the highest mutation rate (50%) in plasma ctDNA and paired liver tissue biopsy. This study demonstrated a poor disease-free survival (DFS) of patients with detectable circulating ctDNA mutations after surgery when compared to those in which mutations were not detected (17.5 months vs. 6.7 months, respectively). The authors suggest that ctDNA mutation panels can be used to classify tumours regarding their proliferative status such as Wnt pathway activation. In contrast, the frequency of mutations varies significantly in different cohorts, with the chromatin remodelling gene **ARID1A** being reported with the highest mutation rate (n=6/51, 11.7%) in ctDNA of HCC patients in a European cohort [59]. Other mutations identified in ctDNA of HCC patients comprise the oncogenes **KRAS**, **NRAS** and **TERT**, and the tumour suppressor **AXIN1**, which are involved in several major tumour progression pathways (e.g. MAPK/RAS, telomere maintenance, p53 signalling and Wnt-β catenin pathway) [60-62]. In addition to genetic alterations, altered DNA methylation patterns, notably characterized by global hypomethylation and region-specific hypermethylation, are early events during carcinogenesis [63]. Cai et al. performed a genome-wide mapping of 5-hydroxymethylcytosines (5hmC) using plasma cfDNA collected from a Chinese cohort (n=1,204) and developed a 32-gene panel capable of distinguishing early HCC patients from high-risk individuals (e.g. chronic hepatitis and/or liver cirrhosis patients) based on 5hmC distribution. This novel panel significantly outperformed AFP measurement, being able to identify HCC patients with <20 ng/ml AFP levels who otherwise would be wrongfully diagnosed [64].

Determining the methylation status of oncogenes and tumour suppressor genes in ctDNA is a method for understanding tumour biology and guiding therapeutical strategies. For instance, Ras association domain family 1 isoform A (**RASSF1A**) hypermethylation was detected in the serum of 93% (59 out of 63) of HBV-related HCC patients in comparison to only 8% (4 out of 50) of healthy individuals [65]. Considering AFP-negative tumours present a clinical challenge in the diagnosis of HCC, Lu et al. demonstrated that the hypermethylation of **RASSF1A**, **COX2** and **APC** genes in plasma ctDNA can be used to identify HCC patients with <20 ng/ml AFP, besides being negatively correlated to tumour recurrence and overall survival [66]. Altogether, these studies indicate that cell-free circulating DNA is useful not only to identify patients in early stages of the disease but also to be used as prognostic markers (see Table 1).

3.1.2 Circulating microRNA in hepatocellular carcinoma

In 2018, Xia et al. analysed transcriptomic datasets from The Cancer Genome Atlas (TCGA), the Gene Expression Omnibus (GEO), and Oncomine from 920 HCC tissue samples. They identified 23 genes significantly altered in HCC patients, targeted by 9 differentially expressed miRNAs and 21 lncRNAs [76]. Xia et al. were unable to perform this analysis in serum due to the lack of publicly available data. In a separate study using RNA-seq, the upregulation of oncogenic miRNAs miR-21 and miR-10b was detected in paired tissue and serum samples from HCC patients (n=89), and miR-21 correlated with poorer prognosis [77]. Lin et al. developed a serum miRNA panel – miR-29a, miR-29c, miR-133a, miR-143, miR-145, miR-192, and miR-505 – that outperforms AFP and correctly diagnosed AFP-negative HCC. Samples were prospectively collected from patients under surveillance for HCC, and the panel identified preclinical HCC 12 months before diagnosis [78].

Elemeery et al. analysed the serum of 200 HCC patients in comparison to 200 cirrhotic individuals. Two miRNAs, miR-34a, miR-221, were upregulated in HCC, whereas five others were downregulated, miR-16, miR-23-3p, miR-122-5p, miR-198, miR-199a3p [79]. MiR-122, an EMT-regulator abundant in the liver, is down-regulated in HCC tissue and serum. Low miR-122 expression is associated with metastasis and the restoration of its expression sensitizes HCC cells to sorafenib, suggesting its use as a biomarker for prognosis and treatment [80, 81]. Both miR-122 and anti-miR-21 were investigated as potential therapies for HCC using miR-loaded nanoparticles delivered directly into the tumour. The authors reported an immunomodulation of protumoral (IL-1α, IL-1β, IL-6 and IL-17) and antitumoral (IL-2 and IL-12) cytokines, enhancing the effect of doxorubicin [82].

An et al. reported the diagnostic value of serum miR-375, miR-10a, and miR-423, which are upregulated in the sera of HCC patients. All four circulating miRNA included in this study decreased after the removal of the tumour, highlighting their potential to be used as biomarkers to monitor recurrence after surgery [83]. Other plasma microRNAs usually overexpressed in HCC include miR-20a-5p, miR-25-3p, miR-30a-5p, miR-92a-3p, miR-132-3p, miR-185-5p, miR-320a and miR-324-3p [84]; whereas miR-218 [85], miR-1246 and miR-3126-5p [86] are downregulated. The absence of studies validating miRNAs as biomarkers in a large cohort, and the high costs for isolating miRNAs, primers and amplification limit their application for screening and diagnostic purposes. In addition, it is interesting to note that the variability of miRNA targets across these various studies suggests the protein profiles may differ between serum and tissue; it indicates that the processing of blood, predominantly in the kidneys, may alter circulating miRNA profile.
3.2 Circulating Tumour Cells (CTCs) detection and characterization

Circulating tumour cells (CTCs) are cells that are shed from a primary tumour or metastatic lesion and enter the circulatory system. CTCs can be isolated from peripheral blood and used to determine therapeutic targets and biomarkers because they mimic tumour properties [87]. Several limitations have halted the advances in the clinical use of CTCs. First, early stages of cancer present significantly lower levels of CTCs; thus, CTC count tends to be proportional to the tumour volume. In addition, only 0.01% of the cells that enter the circulation survive to produce metastasis. Finally, CTC populations are highly heterogeneous regarding phenotype and genotype which makes it challenging to establish standard detection methods [44, 88].

Recent technologies for isolating CTCs can be divided into two categories: physical and biological methods. The former relies on physical properties of the cell such as density, deformability, electric charge and size, and can be isolated using filtration or ficoll centrifugation, for instance [88]. In contrast, biological approaches rely on tumour-specific biomarkers which include cell receptors (HER2), epithelial markers (EpCAM), and site-specific antigens such as the prostate-specific antigen (PSA). Currently, the CellSearch™ system is the only FDA-approved method for isolating CTCs, which captures tumour cells using anti-EpCAM-coated magnetic beads [89]. This method presents a limitation because, although EpCAM is expressed in most epithelial-derived cells and not in blood cells, highly metastatic tumour cells undergoing epithelial-mesenchymal transition (EMT) are not isolated. Consequently, more recent devices using microfluidic chip systems and nanotechnologies in combination with surface biomarker detection have been proposed [87, 90].

3.2.1 CTCs in hepatocellular carcinoma

Schulze et al. detected CTCs in the peripheral blood of 18 out of 59 HCC patients (30.5%). Following their isolation using the CellSearch™ System, CTCs were stained for cytokeratin (CK) as a cancer marker, as well as with CD45 to exclude haematopoietic cells. The authors reported an association between CTC detection and tumour BLCL stage, with stage C (n=11/19, 57.8%) significantly higher than stages A (n=1/9, 11.1%) and B (n=6/31, 19.3%). CTC-positive patients had shorter overall survival (460 days) compared to those without CTCs (746 days) [91]. The characterization of EpCAM-positive CTCs was performed by Kelley et al., who first reported the isolation and the genomic characterization of CTCs using Whole-Genome Amplification followed by next-generation sequencing. A total of 58 somatic mutations were detected in CTC-derived DNA, including TP53 and PTEN variants characteristic of liver cancer, which were further confirmed in matching peripheral blood mononuclear
cells (PBMC) and tumour tissue samples [92]. Genetic alterations were also reported by Xu et al., who isolated CTCs from 69 out of 81 HCC patients (85.1%). Two patients presented HER-2 gene amplification with chromosome 17 gain, and six showed TP53 deletion evaluated using fluorescence in situ hybridization (FISH) [93].

HCC cells are highly heterogeneous with only a small percentage (0-35%) presenting EpCAM expression, and a group of EpCAM-negative cells can be found even within tumours considered positive for this marker [94]. A multimarker combination has been proposed as a method to detect cells that accurately reflect tumour heterogeneity. Qi et al. isolated CTCs from 101/112 HCC patients using the CanPatrol™ System and further characterized tumour cells using RNA in situ hybridization targeting EpCAM, vimentin and Twist to capture cells undergoing EMT. Interestingly, CTCs were detected in two out of the twelve HBV patients in the control group of the study, who were followed every 1-2 months and developed small HCC nodules no longer than 5 months after sample collection [90]. In 2018, mesenchymal CTCs were detected in the blood of HCC patients using multiplex RNA in situ hybridization (RNA-ISH) targeting epithelial (CK8, CK18, CK19 and EpCAM) and mesenchymal (vimentin and Twist) markers. In a follow-up approximately 30 days after surgery, patients who had higher CTC counts presented increased tumour recurrence rates and shortened disease-free survival. The authors compare the prognostic value of EpCAM-positive and mixed (epithelial + mesenchymal) CTCs, showing that the later provides more accurate outcomes [95]. Other HCC-specific markers used in CTCs studies include glypican-3 (GP3), CD44, glutamine synthetase (GS), and HepPAR-1 (see Table 2) [44, 90].

3.3 Proteomics and circulating protein biomarkers for HCC

Currently, the use of protein biomarkers in HCC diagnosis is limited to AFP, however, its suboptimal diagnostic performance led the American Association for the Study of Liver Diseases (AASLD) to no longer require AFP testing as part of the diagnostic evaluation [20, 43]. Proteomics can identify and measure protein abundance in several fluids, therefore it could be used in the development of novel biomarkers. Recent efforts towards establishing HCC proteome databases were made possible by advances in high-throughput mass spectrometry-based tools including matrix-assisted laser desorption/ionization-time of flight MS (MALDI-TOF), or gel-based techniques such as 2-dimensional difference gel electrophoresis (2-DIGE). [100]. Currently, protein identification is achieved either by performing a proteolytic digestion of proteins into peptides prior to mass spectrometry analysis, also known as a “bottom-up approach”; or by using separation methods to analyse intact proteins in complex biological samples, which is known as “top-down approach” [101].

Yang et al performed a comparison between the secretome of the primary culture of paired HCC cells and non-tumorous adjacent liver tissue and identified 1,365 differentially abundant proteins. Among these, 4 proteins were validated using plasma samples of 179 HCC patients, in which circulating MMP-1 and osteopontin (OPN) showed a greater ability to differentiate HCC patients from those with decompensated cirrhosis than AFP measurements [102]. Using an untargeted MS approach, Tsai et al. compared sera protein composition of 97 HCC and 118 liver cirrhosis patients following the depletion of high-abundant proteins. The authors identified 5 proteins associated with HCC significantly different between cohorts – apolipoprotein A-II (APOA2), clusterin (CLU), complement factor B (CFB), apolipoprotein C (APOC) and vitronectin (VTN) – in addition to 11 new biomarker candidates confirmed using targeted multiple-reaction monitoring-mass spectrometry (MRM-MS). Together with AFP, this 5-protein panel was used to detect HCC with an AUC of 0.80 [103]. Other protein biomarkers discovered using proteomics include CD14 [104], clusterin (CLU), inter-α-trypsin inhibitor heavy chain H4 (ITIH4), apolipoprotein B-100 (APOB-100) [105], FOS-like antigen 2 (FOSL2) and fibrinogen gamma chain (FGG) [106]. However, most of these consist of case-control studies aiming to develop clinical assays, thus lacking retrospective longitudinal results to evaluate their feasibility in a clinical setting.

Proteomics findings can also be used to monitor response to liver cancer therapy (see Table 3). Yu et al. collected blood samples from 180 HCC patients before and after doxorubicin-based TACE and evaluated changes in protein composition using MRM-MS. Five proteins - leucine-rich alpha-2-glycoprotein (LRG1), serum amyloid P-component (APCS), cholinesterase (BCHE), complement component 7 (C7), and ficolin-3 (FCN3) – were significantly different between patients with a complete response to TACE and those in which the treatment was ineffective [107]. Liu et al. identified 27
differentially expressed proteins in serum samples of HCC patients (n=16) and healthy individuals using isobaric tags for relative and absolute quantitation (iTRAQ)-based LC-MS/MS, most of which were associated to the nuclear factor-κ beta (NFκB) and ERK1/2 pathways. The follow-up of patients who underwent curative resection revealed that increased levels of phosphoglycerate kinase 1 (PGK1) three, six or nine months after surgery are positively correlated to tumour recurrence. Thus, PGK1 could be used as a prognostic marker in combination with AFP [108]. Shen et al. reported an increase in the serum levels of ficolin-3 in patients (n=52) who respond to radiofrequency ablation therapy, with 3-year disease-free survival rates of 50.0% compared to only 22.7% in the low ficolin-3 group [109]. These results are interesting considering the immune-related properties of ficolin-3 and the crescent interest in combining locoregional therapies and immunotherapy [110]. Altogether, these findings suggest that targeted proteomics-based models can be used to predict clinical outcomes and to help determine suitable therapeutic strategies for HCC.

In addition to AFP, the use of other serum proteins for disease surveillance, diagnosis and prognosis of HCC has been proposed. Choi and co-authors evaluated the surveillance potential of serum AFP, lectin-reactive AFP (AFP-L3), and des-γ-carboxy prothrombin (DCP) in 689 patients with liver cirrhosis and/or viral hepatitis B[111]. In the 42 patients who developed HCC, serum AFP and AFP-L3 levels were significantly increased up to 6 months before the diagnosis, while DCP was unaltered. At diagnosis, the diagnostic performance of AFP (AUROC=0.77), AFP-L3 (AUROC=0.73) and DCP (AUROC=0.71) were inferior to the combination of AFP and AFP-L3 (AUROC=0.83, sensitivity=79%, and specificity=87%) [111]. Other combinations reported for the diagnosis of HCC are dickkopf-1 (DKK-1), DCP and AFP (sensitivity=93%, specificity=78%)[112]; and AFP and DKK-1 alone (sensitivity=78.4%, specificity=72.5%)[113]. Those studies demonstrate that combining biomarkers is an interesting strategy to overcome the suboptimal performances of the circulating proteins currently used for the early detection of HCC.

Besides blood, other body fluids have been investigated using comprehensive proteomic analysis. Zhang and co-authors evaluated paired liver tumour tissue and hepatic interstitial fluid from 44 liver cancer patients, 17 individuals with other liver diseases and 30 healthy volunteers using iTRAQ-MS [100]. They identified two significantly increased proteins – secreted protein acidic and cysteine-rich (SPARC) and thrombospondin-2 (THBS2) – in the interstitial fluid of HCC patients, both associated with the ECM in the tumour microenvironment. The diagnostic power of these biomarkers was investigated in the sera of 17 HCC patients, in which they were able to discriminate HCC patients from healthy controls both alone (SPARC: AUROC=0.88, sensitivity=80%, specificity=93%; THBS2 AUROC=0.91, sensitivity=80%, specificity=93%) and combined (AUROC=0.97, sensitivity=86%, specificity=100%) [100].
Ding et al. compared the salivary protein composition of 15 HCC patients and 15 healthy controls using iTRAQ-MS. Out of the 113 differentially abundant proteins identified between the cohorts, only superoxide dismutase 2 (SOD2) was confirmed by ELISA with an AUROC value of 0.9082 for detecting HCC [114]. As highlighted by the authors, the lack of liver tissue samples to validate those findings is a limitation to proteomics studies regarding circulating biomarkers. In 1993, You and co-authors developed an ELISA assay to detect salivary AFP levels. They reported a strong correlation (r=0.978) between salivary and serum levels of AFP and increased salivary AFP in HCC patients compared to healthy subjects (1,367.8 ng/L vs 14.3 ng/L, respectively) [115]. These findings, however, were not translated into the clinical management of HCC.

3.4 Metabolomics and HCC

The profiling of metabolites in biofluids, known as metabolomics, provides information on systemic alterations that are related to the onset or the progression of liver cancer [121]. In recent years, metabolomic analysis were performed using nuclear magnetic resonance (NMR), and a combination of gas chromatography (GC), liquid chromatography (LC), and mass spectrometry (MS)-based techniques. Kim and co-authors assessed the serum metabolite composition of 53 HCC and 47 cirrhosis patients [122]. They developed a panel consisting of 5 metabolites – methionine, proline, ornithine, pimelylcarnitine, and octanoylcarnitine – that reliably distinguished HCC patients from those with cirrhosis (AUROC=0.94), outperforming the measurement of AFP (AUROC=0.78). They also identified the urea cycle, ammonia metabolism, and amino acid recycling as important pathways in the progression from cirrhosis to liver cancer [122]. In another study comparing plasma metabolites from HCC (n=63) and cirrhosis (n=65) patients, 11 metabolites were significantly altered between the cohorts [123]. The combination of these metabolites and clinical covariates, including AFP levels and Child-Pugh score, lead to a better diagnostic performance than AFP alone [123].

Considering liver cancer is related to a number of liver conditions, several authors have used metabolomics to understand etiology-specific mechanisms of carcinogenesis. Gao and co-authors compared the serum metabolite composition of 49 HBV, 52 liver cirrhosis (LC) and 39 HCC patients, and identified a metabolic perturbation associated with energy metabolism, amino acid synthesis and redox balance across the groups [124]. They conclude that metabolites can be used as disease-specific biomarkers, namely phenylalanine, malic acid and 5-methoxytryptamine (HBV vs. healthy individuals), palmitic acid (LC vs. HBV), and asparagine and β-glutamate (HCC vs. LC) [124]. A variety of other tissue, serum, plasma and urine metabolites have been reported, however, their clinical utility remains under debate and further validation studies are necessary [125].

3.5 Extracellular vesicles

Extracellular vesicles (EVs) are membranous vesicles that are released by cells under physiological or pathological conditions. They may carry cargo such as membrane or cytosolic proteins, lipids, and various types of genetic material (DNA, mRNAs, miRNAs and other ncRNAs). Previously classified as cellular debris, EVs are currently considered mediators of intercellular communication. Therefore, protein- or RNA-loaded EVs are incorporated into the target cell via fusion with the cell membrane, potentially causing changes in phenotype [126]. EVs are classified according to their origin and size: exosomes are vesicles typically ranging from 30 to 150 nm in diameter mainly derived from endosomal
membranes, and released via exocytosis; whereas microvesicles (MVs) are larger particles (50 to ~1300 nm) formed by the direct budding from the plasma membrane [126]. In liquid biopsies, circulating tumour-derived exosomes are isolated using sucrose-gradient separation and ultracentrifugation, the size and number of exosomes are assessed using transmission electron microscopy (TEM) and nanoparticle tracking analysis (NTA) and further confirmed using specific markers (e.g. CD9, CD37, CD63, ICAM-1 and integrins) which can be detected by western blot or flow cytometry [127]. In contrast to MVs, the role of exosomes in liver cancer has been extensively investigated (see Table 4). The majority of targets found were miRNAs and lncRNAs further emphasizing the importance of circulating RNAs as diagnostic markers. As for recent studies, HSP90B1, VCP and ALIX were the only proteins reported with differential abundance in HBV-positive HCC patients [128].

3.5.1 Circulating tumour-derived exosomes in HCC

In the last decade, several circulating HCC-derived exosomes containing miRNAs, mRNAs, lncRNAs and proteins have been identified. Recent studies regarding the use of exosomal biomarkers in HCC are summarized in Table 4. Mjelle et al. isolated exosomes from 145 HCC patients using size-exclusion chromatography and performed a comprehensive transcriptomic analysis using RNA-seq. They reported a global increase of miRNA expression in HCC patients, as well as 40 miRNAs significantly different in this cohort compared to healthy individuals. The liver-specific miR-21 was 4-fold upregulated and correlated with a poor prognosis. The authors also determined specific miRNA and mRNA signatures associated with clinical features such as HBV-infection status and hepatic cirrhosis, indicating that exosomal RNA can be used as prognostic markers for HCC as well as to guide treatment protocols based on tumour molecular background [77]. Similarly, Min Shi et al. demonstrated that miR-638 can be used both for the diagnosis and prognosis of HCC. They collected serum samples from 126 HCC patients and 21 healthy subjects and found that not only exosomal miR-638 expression was significantly lower in HCC patients in comparison to control subjects but also that patients with low miR-638 presented expressively higher tumour size, tumour-node-metastasis (TNM) stage and had reduced 5-year overall-survival rates [129]. Other dysregulated miRNAs have been reported in serum exosomes of HCC patients, such as miR-18a, miR-221, miR-222, miR-224, miR-101, miR-106b, miR-122, miR-195, which can distinguish HCC from viral hepatitis and hepatic cirrhosis [130].

A successful application of an exosomal RNA-based panel to detect HCC was performed by Gwad and co-authors, who evaluated changes in exosomal lncRNA-RP11-51315.6, miR-1262, and RAB11A mRNA expression between patients with HCC, chronic hepatitis C and healthy individuals using qRT-PCR. The panel showed good diagnostic performance (96.7% sensitivity and 95% specificity) to discriminate
individuals with HCC. These RNA biomarkers were shown to independently predict tumour recurrence during a 44 month follow-up period [131]. Despite recent technical advances, there are no standard protocols to isolate and characterize the cargo of extracellular vesicles available, which halts their clinical application.

4. CONCLUSION

The blood-based analysis of solid tumours has rapidly developed in recent years; however, the application of these findings still falls behind for HCC in comparison to other cancers. Liquid biopsies could improve HCC management in two main ways. First, biomarkers such as ctDNA, circulating RNAs and CTCs can provide knowledge regarding the genetic landscape of liver tumours, evidencing driver mutations and potential druggable targets [67]. Second, it can improve surveillance by allowing serial sampling from the same patient. The dynamic evaluation of these biomarkers provides valuable information regarding tumour progression, response to therapy, drug resistance and cancer recurrence [44]. As liquid biopsy remains an innovative field, further research is necessary to validate the potential of minimally invasive biomarkers in the diagnosis and prognosis of hepatocellular carcinoma. Further research is required to compare liquid biopsies to the tissue microenvironment in the liver. In addition, the efficacy of a liquid biopsy to aid in and improve on current HCC diagnosis and management strategies require further validation.
