Physical activity and obesity in children

Andrew P Hills,1 Lars Bo Andersen,2,3 Nuala M Byrne4

ABSTRACT
Globally, obesity is affecting an increasing proportion of children. Physical activity plays an important role in the prevention of becoming overweight and obese in childhood and adolescence, and reducing the risk of obesity in adulthood. Puberty and the following adolescent period are acknowledged as particularly vulnerable times for the development of obesity due to sexual maturation and, in many individuals, a concomitant reduction in physical activity. In many Western settings, a large proportion of children and adolescents do not meet recommended physical activity guidelines and, typically, those who are more physically active have lower levels of body fat than those who are less active. Active behaviours have been displaced by more sedentary pursuits which have contributed to reductions in physical activity energy expenditure. Without appropriate activity engagement there is an increased likelihood that children will live less healthy lives than their parents. Owing to the high risk of overweight adolescents becoming obese adults, the engagement of children and adolescents in physical activity and sport is a fundamental goal of obesity prevention.

INTRODUCTION
The rising prevalence of childhood obesity is a serious concern in developed countries1 and increasingly in many parts of the developing world.2 3 It is interesting to note that based on recent data from Sweden, Denmark and Norway, which show that childhood obesity has not worsened since the year 2000, it may be possible to stop the epidemic.4–6 The most significant long-term consequence of obesity in childhood is adult obesity and its related comorbidities.7 An extensive body of research indicates a higher risk of overweight and obese children becoming obese adults than their normal-weight counterparts8–12 and a major contributing factor is low levels of physical activity. Obesity in adolescence also predicts later mortality.13 Physical activity is essential for the normal growth and development of children and adolescents,14 15 plays an important role in the prevention of becoming overweight and obese in childhood and adolescence, and reduces the health risks of the condition.16 However, Western society actively discourages physical activity by decreasing the opportunities to expend energy17 and, in many settings, a large proportion of children and adolescents do not meet recommended physical activity guidelines. Evidence also suggests that obese youngsters are less physically active than the non-obese18–19 and spend more time in sedentary pursuits, such as watching television and using other electronic media.20 21 It is logical to suggest that if such pastimes continue to displace physical activity and exercise, there is an increased risk of children becoming overweight or obese.22 Without appropriate involvement in physical activity, there is an increased likelihood that children will live less healthy lives than their parents.23 As obesity is already a health risk in childhood because of its association with a clustering of cardiovascular disease (CVD) risk factors and atherosclerosis is believed to progress throughout life,24 the engagement of children and adolescents in physical activity and sport is a fundamental goal of obesity prevention.

This review provides an overview of the relationship between physical activity and obesity in children. Physical and psychosocial health problems associated with excess body fat are highlighted, along with a consideration of the key determinants of obesity. If childhood obesity is to be reduced, greater attention needs to be paid to opportunities for all youngsters, irrespective of size and shape, to engage in physical activity and sport.

OBESITY AND PHYSICAL HEALTH PROBLEMS
A number of potential health consequences are associated with excess body fat during the growing years and, without effective intervention, the risk of ill health escalates throughout the adult years.25 Health problems may include CVD and metabolic, gastrointestinal, pulmonary, orthopaedic, neurological, psychological and social disorders.25 26 Specific examples include a predisposition to type 2 diabetes and liver disease, and risk factors for CVD, asthma, sleep apnoea and impaired mobility.17 Andersen et al26 27 have referenced the clustering of risk factors in this population, along with lower levels of physical activity, as causes. A recent paper28 suggested that there may not be a direct relationship between childhood obesity and cardiovascular risk factors in adulthood but instead an indirect relationship through the tracking of obesity from childhood to adulthood.

OBESITY AND PSYCHOSOCIAL HEALTH PROBLEMS
In addition to short- and long-term physical health problems, obese children and adolescents are likely to suffer poorer psychological28 and social health than their normal-weight peers (low self-esteem and self-concept,29 reduced quality of life,30–32 depression1 and social discrimination).

SUSCEPTIBILITY AND PREDISPOSITION TO OBESITY
Being overweight and obese results from an energy imbalance; a disruption between energy consumed in food and drink and energy expended in physical activity and exercise. The steady increase in
overweight children and childhood obesity in recent decades may be the result of an increase in energy intake, a decrease in energy expenditure or, more logically, a combination of both. Obesity is further complicated by the complex interaction between diet, physical activity and metabolic and genetic factors in an environment that encourages consumption of high-energy foods and discourages expenditure of energy. Although genetic or transmissible factors account for much of the individual variability in body size and shape and influence one’s propensity to manage body weight, the major environmental contributor to an increase in fat deposition is a positive energy balance. It is important to highlight that one of the main effects of physical activity is not energy expenditure per se, but rather the effect it has on improved appetite regulation.

A complex set of individual, family- and community-level factors affect weight status in children and influence children’s decision-making regarding energy intake and expenditure. Many of the factors that account for the significant recent increases in the prevalence of obesity may have also changed over time. These include an increase in the perceived risks of physical activity and sports participation, changes to the physical environment, a scarcity of time, prioritising academic versus more active pursuits, and, potentially, cost. Similarly, the value people place on physical activity and exercise may also have changed over time. Changes in societal attitudes about body size and shape and body image may have also influenced physical activity practices; for example, there is an increased polarisation of the population to more obese and very lean children.

One of the useful frameworks presented to conceptualise the many factors associated with childhood obesity was developed by Davison and Birch. The framework includes three main categories: Child characteristics and behaviours: genetic predisposition plus energy intake, physical activity and sedentary behaviours Parenting styles and family characteristics: influence children’s behaviour Community, demographic and societal characteristics: influence the behaviours of children, parents and families. Includes socioeconomic status, education, ethnicity, advertising and the physical environment.

Physical activity and obesity

Physical activity, and diet, are the cornerstones of obesity prevention and management. Optimal nutrition in combination with regular physical activity during the growing years increases the likelihood of a healthy pattern of physical maturation consistent with the genetic potential of an individual child. Physical activity is beneficial at all stages during the formative years and active play is important in physical, mental and social aspects of growth and development, helping to set a pattern of participation in physical activity across the lifespan.

A range of environmental factors including less active transport and the changing nature of school-ground facilities have resulted in the reduction or removal of many physical activities from our contemporary lifestyle and thereby contributed to the childhood obesity epidemic. Levels of habitual physical activity in many young people and adults are lower than they were in the past and this has contributed to both a reduction in physical activity energy expenditure and, as a consequence, total energy expenditure. Accordingly, normal levels of habitual physical activity are lower than required to maintain a healthy body weight.

Despite acknowledged challenges in the objective assessment of physical activity in children, there is evidence that many young people participate in considerably less physical activity than is recommended for health. Of particular concern is that physical activity levels decline in the period of transition from childhood to adolescence, between the ages of 9 and 15 years. Despite data on the relationship between physical activity and obesity in children and adolescents being inconsistent, most studies of habitual physical activity in children suggest that the overweight and obese are less active and have poorer fundamental movement skills than their normal-weight counterparts. There is also consistent evidence that boys are more habitually active than girls and even at the age of 6 years boys have lower skinfold thickness, and that obese children favour participation in sedentary behaviours.

Low levels of physical activity during childhood combined with obesity contribute to substandard health-related fitness and reduced confidence in the ability of such children to participate in sport and physical activity. In contrast, enhancement of motor skills has the potential to improve a child’s motivation to participate in physical activity through improved self-esteem and increased enjoyment.

Physical activity has a direct relationship with the healthy weight status of children through higher levels of energy expenditure. However, physical activity level is also directly associated with health outcomes of children; low levels of physical activity are typically associated with an increased risk of cardiometabolic and vascular diseases. Therefore, encouraging both normal-weight and overweight children to increase their levels of physical activity and exercise and reduce their sitting time will help to avoid excess weight gain and associated health risks. In adults, physical inactivity and obesity have similar health consequences. Importantly, obese individuals who are physically active may have lower morbidity and mortality than their normal-weight but sedentary counterparts. A recent systematic review of adult studies by Fogelholm indicated that the risk for all-cause and cardiovascular mortality was lower in individuals with high body mass index (BMI) and good aerobic fitness, compared with individuals with normal BMI and poor fitness. In contrast, individuals with a high BMI, even with high physical activity, have a greater risk for the incidence of type 2 diabetes and the prevalence of cardiovascular and diabetes risk factors, compared with individuals with a normal BMI and low physical activity.

Fogelholm proposed two major links between physical activity and obesity. First, physical activity may prevent weight gain by increasing daily energy expenditure and potentially by suppressing appetite. A common finding in cross-sectional studies is the association between lower prevalence of obesity and higher physical activity. This finding contrasts with the inconclusive findings reported in intervention studies. An explanation for the strong association between physical activity and obesity in cross-sectional studies is ‘reciprocal causality’ such that physical activity enables individuals to control their weight easier by increasing energy expenditure. In contrast, unsuccessful weight control reduces aerobic fitness, increases musculo-skeletal pain and increases discomfort, which results in physical activity being more challenging. Health is the second major link between physical activity and obesity cited by Fogelholm including risk of CVDs, type 2
diabetes and some cancers. Most importantly, each of the health risks is reduced by adequate levels of physical activity and at least moderate cardiopulmonary fitness.

Physical activity and fitness in childhood and adolescence is also associated with numerous health benefits, despite being deficient in many settings. Appropriate levels of physical activity can confer fitness while lowering the risk of obesity and health risks associated with increased fatness. Physical activity also contributes to greater bone density, reduced clustering of CVD risk factors, improvement in body composition and assists in maintenance of weight loss.

Improvements in our understanding of the factors that contribute to excess weight gain stems from the tracking of adiposity and lifestyle behaviours from infancy through childhood, adolescence and into adulthood. Between 2 and 5 years of age, overweight children have four times the risk of normal-weight children of being overweight as adults and the strength of the association increases throughout the growing years.

There is growing evidence that the health of children in most Western countries has deteriorated in recent decades. Consistent with this trend is the increased prevalence of childhood overweight and obesity, declines in physical performance and more youngsters with very low fitness. Paradoxically, indications from the literature are that children and adolescents in many countries are sufficiently active. However, much of this evidence is based on self-reported physical activity data and there is a paucity of national data in many countries, including Australia. Based on objective measures, Colley et al. recently reported that physical activity levels of Canadian children and youth are very low. In Australia, numerous studies have reported reductions in active transport in 5–14-year-old children between 1971 and 2003, and significantly lower levels of moderate- to vigorous-intensity physical activity. Further, examinations of the relationship between physical activity and childhood obesity have reported significant inverse associations between physical activity levels, BMI and body fat.

Despite the need for more evidence, it is critical that all children and adolescents accumulate sufficient physical activity each day. The recent WHO global recommendation on physical activity for health recommends children and adolescents aged 5–17 years participate in at least 60 min of moderate- to vigorous-intensity physical activity every day. Most importantly, the recommendation acknowledges that this volume of exercise must be in addition to the activities of daily living, calculated using objective measures as 35–40 min moderate- to vigorous physical activity. This recommendation is consistent with other countries including Australia, the UK and Canada. Martinez-Gomez et al. have recently reported that current physical activity guidelines appear to be appropriate to prevent the accumulation of excess body fat in European adolescents. Like Gutin, they suggest that for obesity prevention, greater attention be paid to participation in vigorous intensity physical activity.

CONCLUSIONS

In conclusion, there appears to be a strong relationship between physical activity and obesity in children and adolescents. Physical activity in children and youths is associated with health benefits, including lower levels of being overweight and obese. Higher levels of activity translate into greater benefits. Although many reports suggest that children’s participation in organised sport and physical activity has increased, incidental physical activity and exercise, including active transport such as walking to and from school, has declined. Similarly, there is weak evidence for the effectiveness of interventions to prevent childhood obesity. This may be due to a range of factors including inconsistent approaches used in systematic reviews, disparities in anthropometric approach, and whether body fat was predicted or measured objectively. Reilly suggests that the ineffectiveness of many obesity interventions relates to targeting behaviour modification at the level of the individual, children, their families or schools, whereas many influences on weight status are broader and include education, food labelling, taxes and transport, as outlined by Nestle et al. From a public health perspective, the promotion of a healthy diet and the encouragement of physical activity and exercise are equally important factors for the maintenance of a healthy weight and body composition and reducing the risk of chronic diseases.
